OPERATIONS FOR RESTORING COMPLETE LACERATIONS OF THE FEMALE PERINEUM THROUGH THE SPHINCTER ANI,

AND THE SUBSEQUENT MANAGEMENT WITHOUT CONSTIPATING THE BOWELS.[1]

BY H. T. HANKS, M.D.,

ASSISTANT SURGEON TO THE WOMAN'S HOSPITAL.

THE necessity of an operation for restoring the female perineum after a complete laceration extending through the sphincter ani, cannot be questioned for one moment by any intelligent physician. The annoyances, mortification, and distress which a woman of fine sensibility endures, when suffering from this accident, are so manifest that the surgeon does not need to ask if the operation is demanded, but rather, can it be successfully performed? Few lesions can exist which will occasion so much mental anxiety and result in so much physical suffering to a lady, as a complete rupture of the perineum through the sphincter ani. The constant fear lest rectal gas and fecal matter may escape, causes her to avoid society, and often to shun her own husband. This mental strain, though exquisitely distressing, is not all, since the support which the perineum and sphincter give in health, being now lost, the liability of a cystocele, prolapsus of the uterus and eversion of the rectum, is very great. And generally one or all of these distressing pathological changes will result from, and be present with, a laceration through the sphincter.

In several of my cases I have found the uterus prolapsed to the ostium vaginæ, while two have been great sufferers from eversion and prolapsus of the bowels. In one recent case, under the care of Dr. Thomas at the Woman's Hospital, this condition of rectal eversion and prolapsus was of so long standing, that it was difficult to determine the exact pathological condition, and the operation for cure was extremely complicated and tedious.

The operation for restoring the perineum and sphincter when completely torn through is difficult. And the subsequent management of the bowels by confining them for eight to ten days, and carefully superintending personally, or by the aid of the nurse, every step in their final evacuation after this period, is so trying that the operation is more often than otherwise a failure, when performed by the general practitioner. Hoping to make some points in the operation more simple, and the after-treatment less te lious to the surgeon and distressing to the patient, I have been led to prepare this paper.

My opportunities to watch the operations and results, at the Woman's Hospital, and of several of my professional friends, where I have been the consulting physician, and those cases coming immediately under my own care in private, and public practice, have given me an excellent field for the study and trial of the best methods of operating, and the subsequent management of the patient. I am convinced that there is a necessity for a better understanding of the different methods of operating, the advantages of each method, the causes and possible chances of failure, and the best course to pursue to insure a successful result in each case. All who have operated several times have had failures; and the most experienced gynecologists have occasionally had only failures, after two or more operations upon the same patient. During the last six months my attention has been particularly called to the uncertainty of a successful result in the ordinary operation and subsequent treatment, even when every condition would seem to be favorable. I have, therefore, taken occasion to look up the notes of my own cases, and to procure statistics from the Woman's Hospital, through the kindness of Drs. W. E. Mosely and H. C. Coe, internes of that institution. In studying these facts I have been surprised at the percentage of failures after the first operation, and can, therefore, see how Barnes can say: "If the rupture extends through the sphincter the difficulty is often serious, and success has sometimes to be pursued in two or more trials."

Schroeder says: "This complicated and difficult operation is not apt to be very successful." One of the most industrious, painstaking, and distinguished gynecologists in America stated in my presence that, without the best attention and personal vigilance of a trained nurse, failure was the rule. Another equally eminent authority confirmed this statement.

The Emmet operation in lacerations extending through the *sphincter ani* only, brings the parts in exact apposition, and when successful, the final result is as perfect a union as could be desired. When, however, the laceration extends through the sphincter and half an inch or more above, in the rectal wall, the so-called Simon operation is more surely indicated for closing the rectum and sphincter, and will give better results. A second operation (Emmet's) may be subsequently required to close the perineum, however.

I shall describe these operations and endeavor to make each step clear and plain.

I shall recommend a new method of securing the ends of the wires, which perhaps is a small matter.

Finally, I shall urge the advantages and importance of keeping the patient's bowels relaxed for two weeks after the operation, which, in my opinion, is the most important factor for success, after a perfect operation has been performed. I am convinced that the usual method of confining the bowels for eight to ten days after the operation was the cause, either directly or indirectly, of more than half my own and my friends' failures.

The operation of closing the perineum and sphincter ani and rectal wall, is really more trying, and one that requires more judgment and skill, and a more thorough knowledge of the anatomy of the parts, than many which seem far more heroic and important.

In order to make the difficult steps of the opera-

[1] Read before the Obstetrical Section of the New York Academy of Medicine, May 25, 1882.

tion which I recommend perfectly plain and more easily understood than is possible from the descriptions in our text-books, I have prepared a number of models[1] and plates,[2] which, though rough exaggerations, will aid me, I trust, in accomplishing this end.

Before performing the Emmet operation, which is recommended for all cases in which the perineum and sphincter ani *only* are involved, there should be careful preparation for one week; and the operation should be avoided here, in New York, during the rough weather of March, or the heat of July and August, and should never be undertaken when the operator is also attendant upon a case of erysipelas, scarlet fever, or diphtheria.

In preparing the patient, she should be brought into the best possible physical condition by a course of tonics, good food, and regular exercise, if possible, preparing her mind as well as body for the operation, by encouraging prospects of a complete recovery.

The operation should be performed from five to seven days after menstruation, and a thorough evacuation of the bowels should be procured daily, for a full week before; at first, for two days, by means of two or more comp. cath. pills, afterward by a daily dose of the comp. liquorice powder; cream tartar, sulphur, and rhubarb; hunyadi water; or a seidlitz powder. Whichever is used, it should be sufficient to move the bowel thoroughly. After thus testing the quantity required, for three or four days, the exact amount requisite to liquefy the evacuations, subsequent to the operation, may be ascertained. By this means the danger of hypercatharsis, as occurred in one of my cases, can be avoided. Three assistants are required; one to administer the ether, and one to steady each leg and separate the thighs. The patient, having been thoroughly prepared as has been described, should be anæsthetized and placed in the lithotomy position before a good light. All hairs in the immediate vicinity of the parts should be removed; after which a thorough examination of the rectum and vagina should be made, as only after this careful inspection will the torn edges of the bowel and sphincter ani be seen, and felt, and the original perineal cicatrix be recognized.

The tenaculum should then be made to seize a portion of the tissue above A, in Fig. 1, upon the patient's left. The tissue, one-eighth of an inch in breadth, thus raised by the tenaculum, should then be dissected off with a pair of curved scissors down to the angle O, cutting sufficiently deep to expose the fibres of the torn sphincter.

A similar dissection should be made from O to A, on the patient's right. This will thus leave denuded the edges of the torn sphincter and rectum. Then a point of tissue should be seized just above A, near B, on the patient's left, and a similar strip should be dissected off with the scissors, until the point B is reached on the right. Similar steps should be taken until the whole perineum is denuded, as represented from AA to GG in Fig. 1, which can always be determined by the cicatrix. After the sphincter and rectum have been prepared, the further denudation for the perineal body may be varied, as may seem most convenient and judicious to the operator, at the time. Great care should be exercised, however, in coming down upon the floor of the vagina upon both sides, to remove all the mucous membrane of the two triangles which are to constitute the denuded space, and united, to form the perineal body.

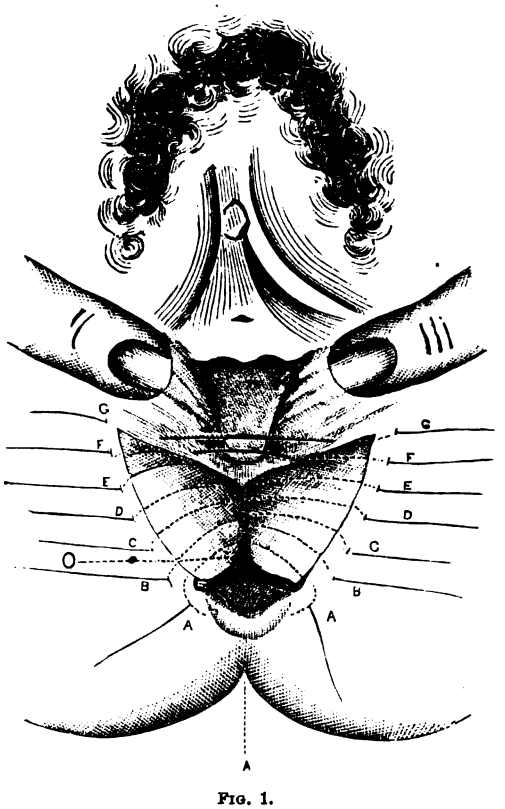

FIG. 1.

In immediate operations, and more *recent* lacerations, after denuding, considerable hemorrhage may be encountered, which can easily be checked by a few moments' pressure with the hæmostatic forceps, or napkin wet in hot water, as a compress. It is very rarely that a bleeding vessel requires to be tied. The parts should be thoroughly sponged with carbolized warm water, the denuded triangles brought together, and carefully compared. If not exactly similar they should be made so before the sutures are introduced. In introducing the wires the experienced operator will use a straight or curved round pointed needle, about two and one-fourth inches in length, held by a needle-holder. The general practitioner, who may perform the operation only at rare intervals, may use a long curved Peaslee needle, which is firmly attached to a handle, and has the eye at the point. Each needle has its advantage. The straight needle is always used by Drs. Emmet and Thomas, and in their hands is exceedingly convenient; but they also use a needle-holder which does not stay closed excepting when held closed by the hand. The curved needle can be used with greater ease by one not accustomed to frequent operations, if only a needle-holder is used which firmly holds the needle, and remains locked until it is desired to draw the needle through on the opposite side.

[1] These models are oval rings of curled hair, covered with chamois skin. The size most convenient is about ten by seven inches. Where the model is to show the denuded surfaces, there should be a second or inner covering for the curled hair. Then the denudation will consist in dissecting away the outer covering. The recto vaginal septum is made by sewing, and thus drawing together the chamois skin covering of the inner side of the ring.

[2] My friend, Dr. J. H. Gunning, has rendered me valuable assistance in preparing the drawings from which these plates were taken.

The Peaslee needle with handle, and the eye at the point, if it could be made as fine as the other kinds, would be exceedingly convenient. But its objection in this operation is its size, and the consequent danger of injuring veins and arteries, and of breaking through the thin rectal wall at the angle O.

Twenty inches of strong, but fine, silk or linen thread should be doubled, and about four inches of the two ends passed, in opposite directions, through the eye of this straight, or curved needle, thus leaving a loop of about six inches from the eye of the needle. Through this loop the end of a No. 26, or 27, silver wire, ten inches in length, may be hooked, and bent sharply upon itself. The needle, thread and wire should be anointed with vaseline.

The left index-finger of the operator should be inserted in the rectum. The point of the threaded needle, firmly held by the needle-holder, should be inserted into the tissue to the left side of the rectum, at A, in Fig. 1. This point should be but a little above the level of the floor of the rectum, in the undenuded tissue, one-third of an inch from the beginning of the point of denudation. The needle is then slowly and carefully insinuated through the tissue back of the torn sphincter, through the edge of the torn rectum, above the angle O. After passing above the angle O in the rectal wall, by pushing the eye of the needle upward, and pressing it against the glutei muscles, and pulling the point downward, with the index-finger in the rectum and the thumb in the vagina, the point may be made to emerge at A, upon the right. This is easy in recent cases, but more difficult in old cases, where atrophy has taken place. In such cases the needle should emerge from the recto-vaginal septum, just above the angle O; then seize it with the needle-holder and draw it through; afterward insert it at the very point of exit and pass it downward to A, on the right, where it should emerge at a point which exactly corresponds to the point of its original insertion on the left. Upon drawing the needle out with the needle-holder, the thread follows, drawing the silver wire with it, and thus the first and most important suture is introduced.

Great care is necessary that the points of entrance and exit are parallel and correspond. The suture BB passes in just above AA, and through the recto-vaginal septum $\frac{1}{16}$ to $\frac{1}{8}$ of an inch above the suture AA at the angle O. Equal care should be exercised to prevent the needle from passing into the rectum as it passes the angle O; also, that it is not exposed at this, or any point, from its points of entrance to the corresponding point of exit. The sutures FF and GG are so inserted as to bring together the upper angles of the triangle. They are therefore seen in the vagina after having been passed through the upper denuded angles.

In Fig. 2 the suture GG is represented as passing down and under the central portion of the lower border of the undenuded portion of the vagina. In Fig. 1, when the parts are brought together by the closing of all the sutures, GG and FF do not draw up the floor of the vagina. In Fig. 2, after the sutures AA, BB, and GG are twisted, the floor of the vagina will be drawn upward by the suture GG, thus covering with healthy mucous membrane a part of the upper and inner portion of the restored perineum.

The two methods should be varied according as there is little, or much, loose vaginal tissue to draw up.

The parts are now ready for the adjusting and twisting of the wires. All of the wires should be fastened at their extremities and drawn upward, excepting AA, and held out of the way by the assistant. The operator should then seize suture AA, separate the extremities, and carefully slide the wire up and down, to see that there is no knot, nor impediment, in the tissue. He should then, with the fingers or the twister, seize the two wires at about two inches from the anus, and twist them carefully. The assistants in the meantime, with two tenaculi, each inserted above the torn extremities of the sphincter, as in Fig. 2, should approximate the edges in exact apposition, while AA is being twisted by the

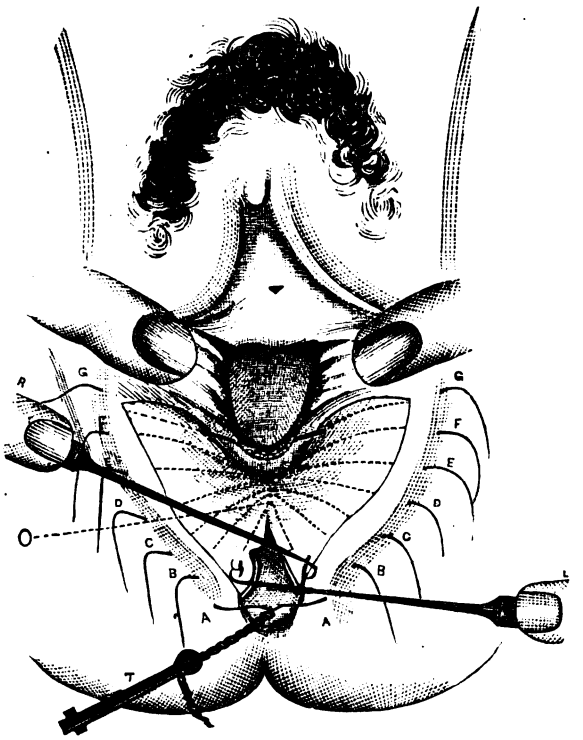

FIG. 2.

operator. Care should here be exercised that what were the outer edges of the sphincter, but are now the upper edges of the approximating sphincter, are made to approach and touch accurately, in order to unite and form a perfect union and a symmetrical circular sphincter.

While being thus held by the tenaculi R L, as in Fig. 2, in exact position by the assistants, the final twisting of the wire AA is completed. It should not be twisted too tightly, or the tissues will be cut through or the parts strangulated. The finger should be introduced in the rectum, that the necessary judgment may be used. At this stage, a careful inspection of the wound in the rectum should be made, both by the finger and the eye. If there is any pouting upward, through the wound, of the mucous membrane of the rectum, it must be crowded back, and the wire twisted somewhat tighter. This most important suture cannot be too accurately adjusted. In twisting the wire BB, the same caution should be exercised by the assistants, under the direction of the operator, in exactly approximating the denuded parts. It will be found to be most convenient in managing the wires CC, etc., to

bring them together by the hand, and twist them once or twice around at their exit, while the final twisting should be completed by the wire-twister. Always use the wire adjuster in the final tightening of all sutures.

To complete the operation in the most convenient and best form, these twisted extremities should be separated into two groups, and smoothed out, and cut off about one and one-quarter inch long, with one wire of each group a little longer than the others. Then a small piece of rubber tubing, one inch in length, should be slipped over the lower group of wires sufficiently far that the extremities may be seen, and these extremities should be fastened to the upper group, and the rubber tubing slipped upward, until it completely covers all the

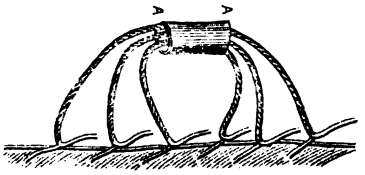

FIG. 4.

sharp ends of the wires, as in Fig. 4; or, what is full better, after separating the wires into two groups, the ends should be joined, and these joined ends covered with tin-foil, or sheet-lead, and the whole flattened, that there may be no sharp points to press into the flesh, when the thighs of the patient are brought together.

The parts should be thoroughly cleansed, a hypodermic injection administered of one-fourth of a grain of morphine, and the patient placed in bed, the knees having been fastened together, not too tightly, by means of a napkin.

These sutures should be cut and removed on the ninth or tenth day.

In cases of laceration of the perineum extending through the sphincter ani, and involving a considerable portion of the rectal tissue above, the Emmet operation is not the best. But the one which has been designated as the *Simon* operation, and represented in Fig 3, if well performed, will give the patient the best chance of a perfect restoration of the parts. The Simon operation is not so frequently performed in America, for perhaps three reasons: First, the Emmet operation has become popularized, especially in New York, from its advocacy by Drs. Emmet and Thomas. Second, the Simon operation requires more time. Third and most important reason is, that the necessity is not so common, as lacerations far up the rectum are less frequent. By examination of Fig. 3 it will be seen that it represents a laceration of an inch and a half above the sphincter ani. If the laceration of the rectum in Fig. 1 extended as far up as in Fig. 3, the wire suture AA would of necessity be much longer, and when the wound would have been closed by tightening wire AA, as in Fig. 2, it would be impossible to suppose that each fibre of the rectum and sphincter had met its severed fellow in exact apposition. But, instead, there would undoubtedly be left an open centre or fistula, or, at least, a semi-closed space, which, like the mouth of a bag closed with a string, would easily admit a probe of moderate size. In other words, the farther up the rectum that the wound extends, the greater the difficulty and the less the possibility, in the Emmet operation, of bringing each circular fibre of the sphincter and rectum in exact apposition with its severed fellow.

For these reasons, and from my own practical experience, which confirms their correctness, I advise and practise the Simon method, in all cases where the laceration extends for more than one-half inch above the sphincter ani.

The Simon operation should be performed as follows: The patient should be thoroughly prepared, and occupy the lithotomy position, as for the Emmet operation.

If the laceration is extensive, two operations are necessary: the rectum and sphincter should be repaired at the first; the perineum restored and closed at another sitting, at least four weeks later.

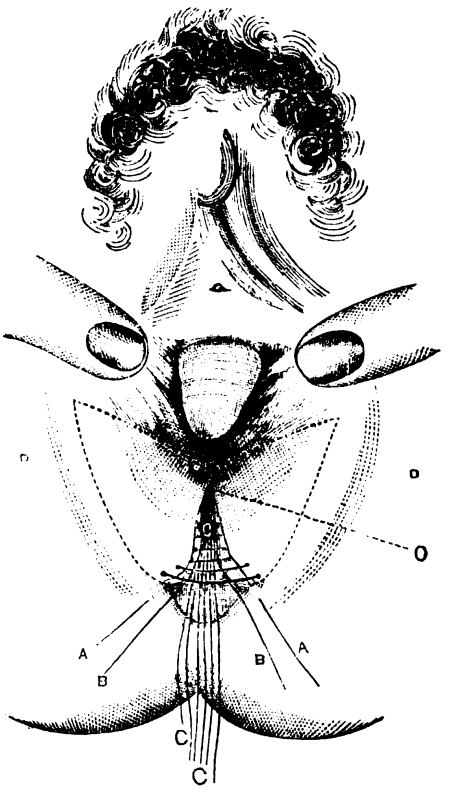

FIG. 3.

Fig. 3 represents the closing of the rectum and sphincter; the dotted line represents the undenuded cicatrix of the lacerated perineum, to be closed later.

The operation consists, first, in carefully denuding the lacerated ends of the sphincter ani and the edges of the torn rectum. Afterward, at the upper angle O, in Fig. 3, upon the right side of the tear in the rectum, a short, fine, curved needle threaded with fine silk should be inserted from below upward, one-eighth of an inch distant from the edge of the laceration, then drawn out through the floor of the vagina, and passed over to the opposite side of the wound, and inserted from above downward, at the same distance from the edge of the laceration as its point of exit upon the opposite side; then carefully draw it through, bringing the edges of the rectum in exact apposition by tightening and tying the sutures from below. One end of the suture may then be cut off, leaving only one

thread lying upon the floor of the rectum. This step has brought the angle O from one-sixteenth to one-eighth of an inch nearer the anus. Similar sutures should be successively passed, at regular intervals of one-eighth of an inch, until the sphincter is reached.

In Fig. 3, the sutures CC are represented as inserted, but not tightened, in order to show their direction, and more distinctly the appearance of the laceration. When the sphincter ani is reached with the sutures CC, each having been tightened in turn, a stronger silk, or a wire suture is needed for the more firm sphincter. In Fig. 3, BB and AA represent the silver-wire sutures which are passed, respectively, through the edge of the sphincter ani, in similar manner to those of the silk, CC, through the rectal tissue above.

As these are tightened, great care should be taken that the assistants, with two tenaculi, as in Fig. 2, bring the edges of the sphincter in exact apposition while the sutures are being twisted by the operator. It will be seen that the Simon operation, as here represented and described, consists solely in bringing each circular fibre of the rectum and sphincter in exact apposition with its fellow, or, as nearly as possible into its original condition before the rupture.

The patient will then be left, if satisfactory union takes place, with only a laceration of the perineum down to the sphincter. The discomforts and mortification, consequent upon the lacerated sphincter, will be entirely removed, and the patient comparatively comfortable, even though the more simple operation of perineorrhaphy should not be subsequently performed.

A hypodermic injection of morphine should be administered, and the same subsequent treatment pursued, as after the Emmet operation. But in this operation the sutures are not to be removed at the expiration of ten days. The two sutures through the sphincter, which are within reach, can be safely removed at about the ninth, or tenth, day. It is advisable to leave the silk sutures, however, for full one month, when the sphincter ani, and the rectal wall, will be strong enough to bear the introduction of the Sims speculum, which it is necessary to use in their removal.

At this time, too, a few, if not all, the fine silk rectal sutures will have sloughed away.

The diet of the patient, after either operation, should be judiciously planned, with a view to proper nourishment and the relaxed condition of the bowels. No medicine will probably be required on the following day. If, however, excessive pain is present, a hypodermic injection of Magendie's solution may be administered. Daily vaginal injections of warm carbolized water should be used—always introducing the nozzle with the greatest care, and holding it steady during the time.

Whatever laxative seems best suited to the patient should be used in sufficient quantity after the second day, to produce liquid evacuations. The same course should be pursued on each succeeding day, until the tenth. If, during this time, there has been excessive heat and pain, the perineum should be frequently douched with carbolized warm water. The urine should be drawn as necessary, for the first two or three days, afterward it may be passed directly into the bed-pan. The patient should *by no means* be allowed to sit upon the chamber, but should keep the recumbent position *invariably* in using the bed-pan for the evacuation of the bowels and bladder.

I have no doubt that others will be equally surprised with myself, at the percentage of failures after performing operations here described I have operated 21 times upon 18 different patients, 3 requiring a second operation. Some of these have been cases of long standing, and where more or less atrophy had taken place about the parts. In several, the rectum was torn for an inch and a half above the sphincter. Only 3 cases were what is called the immediate operation, *i.e.*, directly after the birth of the child. Of these 21 operations there were 13 successful results, and 8 failures, or sixty-two per cent. successful, and thirty-eight per cent. failures. With other later operations there would undoubtedly have been several additional cures, but the disappointment of the patient after a failure is so great, and, when the bowels are finally evacuated, the physical pain is so intense, if they have been constipated, that patients are unwilling to submit to a second operation.

Several of my patients, and those of my professional brethren, have thus been reluctant to receive a second operation, simply from dread of the suffering in the final procedure of opening the bowels, which have been closed for nine days. Let me briefly relate the causes of each of my failures.

Case I.—Mrs. H——, rupture through perineum and sphincter only. Accident with first child. Patient twenty-two years of age, stout, unable or unwilling to bear pain. The Emmet operation, after suitable preparation, was performed two weeks after the accident. Patient undoubtedly took more, and different food than was ordered. Bowels were confined until the eighth day. But when injections of ox-gall and warm water were given at that period, to break down the hard fecal matter, the patient, against my express orders, forced down, until everything that had been gained gave way.

Case II.—The same patient, two months later, submitted to a second operation, with the same nursing, and the same result. She had, I afterward ascertained, surreptitiously eaten unsuitable food, not being well watched, nor controlled, and at the final operation of the bowels the pain was excessive. Although she moves in good society, with every means at her command, the memory of the sufferings which attended the unloading of the bowels, at those particular times, prevents her from consenting to receive another operation.

Case III.—Mrs. O'N——, ruptnre through perineum, sphincter and one-third inch of rectum.

Patient thirty years of age, excellent physical condition. The Emmet operation carefully and exactly performed. In fact, I had come directly from operating on Mrs. S. C. P—— for a similar lesion, which finally resulted favorably, and the same assistants were with me, and the same steps were taken. This case was a sad failure, and was due to the fever consequent upon the operation, change of diet while confining the bowels, and to the collection of hard, dry fecal matter, which, with my own personal superintendence, was expelled, only with intense suffering, by the patient.

Case IV.—Patient of Dr. M——, recto-vaginal rent of one inch; the Simon-Emmet operation performed; patient in excellent condition; bowels confined; moved on the ninth day; sutures removed on the tenth day. Found on next visit the sphincter torn out. Patient undoubtedly had eaten more than was allowed. Is willing to undergo another operation, but having since borne a child, must wait until autumn.

Case V.—Patient of Dr. B——. In good circum-

stances; well nursed. The Emmet operation performed; bowels constipated; failure due to movement of the bowels on the ninth day, which was accompanied with intense suffering.

[A second operation, since performed upon the same patient with bowels kept open, was a perfect success.]

CASE VI.—The sixth failure was a young woman with first child, delivered with forceps. The Emmet operation was performed immediately; bowels confined with opium. Local erysipelatous inflammation developed on the fifth day, and the sutures were cut of necessity.

CASE VII.—The seventh failure, Mrs. M——, was a patient in good circumstances, and carefully nursed. The Emmet operation was performed; the bowels confined. The sphincter gave way on moving bowels ten days after the operation, the sutures being removed on the eighth day.

CASE VIII.—Dr. L——'s patient. The Emmet operation performed two days after confinement; poor preparation; opium given for two days on account of severe pain; laxatives on third and succeeding days, but no movement of bowels until the fifth day, then hard masses of fecal matter tore out sutures.

Thus of the 8 failures there were 7 Emmet and 1 Emmet and Simon operation. Seven patients had the bowels constipated for eight or more days, and one for five days.

Of the thirteen successful operations I will here briefly relate the history of the eight in which the bowels were kept relaxed after the second day. The five successes, *with* constipated bowels, had nothing unusual to which I wish to refer.

CASE I.—Mrs. S——, of Williamsburg, consulted me at the out-door clinic of the Woman's Hospital, in March, 1879. She was a German woman of about thirty years. The rupture, of one year's standing, extended through the perineum, sphincter ani, and full one and one-half inch up the recto-vaginal septum. The rectal mucous membrane was badly everted, congested and prolapsed, rendering exact appreciation of the anatomy of the parts quite difficult. The patient suffered excessively from this eversion and prolapsus, and the consequent loss of control of the bowel, and sphincter, and had been subject, during the last few months, to cataleptic convulsions.

I urged her to enter the hospital, but being unwilling to do so, I consented to operate at her home. Assisted by Drs. W. E. Bullard, J. H. Gunning, and Geo. Thompson, I performed the Simon operation, March 19, 1879.

I passed the sphincter sutures deep, and included a full half inch of the divided perineal body upon each side. The sutures were bent downward over the anus, the ends covered with a bit of rubber tubing. A hypodermic injection of 10 ℥ of Magendie was given. The urine was regularly drawn by Dr. Thompson, then a resident of Williamsburg, or myself. On the third day a teaspoonful of the comp. liquorice powder was given, and a liquid evacuation of the bowels was passed into the bed-pan; no straining was allowed. The same course was pursued until the tenth day, when the two lower, or sphincter sutures were removed, and the result was all that could be desired. At the end of the twenty-fourth day, with the patient in the Sims position, and with the Sims speculum, the rectal sutures were removed.

The woman has since been in excellent health, and although a portion of the perineal body remains unrestored, she feels so well she does not desire to be improved.

CASE II.—My second case in this list was a Mrs. R——, who consulted me for the relief from troublesome symptoms of a lacerated perineum, and sphincter ani. The accident had occurred a few weeks previous, and the family physician, although aware of the lesion, had believed, and so assured, the patient, that it would heal of itself. The Emmet operation, with relaxed bowels, gave satisfactory result.

CASE III.—Mrs. O'N——, No. 3 in list of failures. This second was also the Emmet operation, followed by open bowels after the second day, with perfectly successful result.

CASE IV.—A dispensary patient, in poor general health. Laceration extended full one inch above the sphincter. Drs. Bullard, Hardy, and Ida Bartlett assisted me in the operation. The bowels were opened daily, after the second day, by the comp. liquorice powder. On the fifth day she had a severe and exhausting diarrhœa. Nevertheless, the union was found to be perfect on removing the sutures.

CASE V.—Patient of Dr. F——. The laceration extended through the perineum and sphincter, and one inch up the recto-vaginal septum. The Simon operation was performed six months after the accident. Bowels kept relaxed after the second day. Patient had almost no nursing. The outer sutures were removed on the tenth day. The inner ones, of fine silk, were easily removed at a later date, by gentle traction, without using a speculum.

CASE VI.—Mrs. B——, patient of Dr. B—— (also No. 5 list of failures). The Emmet operation performed. Relaxed bowels, and patient perfectly comfortable through the whole period. Result, perfect success.

CASE VII.—Patient of Dr. B——. Laceration extended through perineum and sphincter only. The Emmet operation was performed three months after the accident. Bowels kept open. Successful result.

CASE VIII.—Patient of Dr. S——. A young woman nursing her first child. Two weeks after delivery, assisted by Dr. S—— and Dr. Hardy, I performed the Emmet operation. The bowels were kept relaxed after the second day. The sutures were removed on the tenth day. The result was highly satisfactory.

SUMMARY.—Thus, of thirteen successful cases, five had bowels confined, eight had liquid evacuations daily, after second day. Of these eight successes with open bowels, I claim that such results could not have been expected, nor obtained, had the bowels been confined. Three of these eight patients were too poor to pay for the necessary nursing, and six lived in crowded tenement-houses.

The statistics of the Woman's Hospital, as furnished me by Drs. W. E. Mosely and H. C. Coe, show that during the last three years there have been 23 patients suffering from lacerations through the sphincter ani, and 48 operations; of these 23 patients, 3 were in poor physical condition and were undoubtedly subjects of syphilis. These 3 patients received 16 operations; 2 were cured and 1 remained a failure. Deducting these 3 unusually bad cases and there remain 20 patients receiving 32 operations. Of these 32, 16 were successful, or about fifty per cent. were successes, and fifty per cent. failures.

These statistics certainly show that the operation when performed in the best regulated hospital, and by the best gynecologists in America, is often a failure. The Emmet operation is generally performed in the

hospital, with occasionally a modification of the Simon, when much rectal tissue is involved; and the bowels have usually been confined for ten days.

We have the best authority for confining the bowels if we wish so to do.

Dr. Sims, in 1855, recommends the constipation of the bowels for two weeks.

Dr. Thomas, in his first edition, advocates constipating the bowels until the sutures are removed on the twelfth day.

Dr. Emmet, in his recent work, minutely describes the operation. He has given more attention to the clinical study of the lesion, and the explanation of the details of the operation, and has accomplished more for the clear understanding of the methods, than any other surgeon. He recommends confining the bowels with opium for six or seven days, and the removal of the sutures on the eighth or tenth.

Dr. William Goodell, of Philadelphia, recommends in his work, that the bowels be locked up for nine days, the sutures cut on the seventh, and the evacuation to be produced by injections of warm soap-suds and sweet oil.

Dr. D. Hayes Agnew keeps the bowels confined with opium, cuts the sutures on the seventh day, and by means of saline laxatives on the eighth to the tenth day, moves the bowels.

Dr. J. Matthew Duncan closes the bowels with opium, cuts the sutures on the seventh, and moves the bowels on the eighth day.

Sir James Y. Simpson, 1877, recommends constipation of the bowels for twelve days.

Baker Brown recommends constipation of the bowels for two weeks.

Graily Hewitt, in the American edition, 1874, recommends constipating the bowels for ten to twelve days.

Schroeder says: "Care should be taken to prevent diarrhœa."

Undoubtedly, many failures outside the hospital are due to imperfect preparations and defective operations, but that these are the principal causes I doubt very much.

Such absolute failures have induced me to look up all the notes of operations which I have performed, and to draw the lessons which these facts teach.

Some of my cases being patients from the poorer classes, who have consulted me at Demilt Dispensary, or at the out-door clinic of the Woman's Hospital, were in no condition to pay me or a professional nurse. I have, therefore, sought for better methods, because dissatisfied with present results, and because I could not act as nurse and surgeon too. I have thus operated several times under unfavorable conditions at their homes. The treatment here described was followed: I gave the comp. liquorice powder, a bottle of magnesia or a seidlitz powder, after the second day, causing a liquid evacuation daily. Among those who were thus treated subsequently there has been *not one failure.*

Although I have not been able to witness the operation, I understand that Dr. Hunter, during the last year at the Woman's Hospital, has injected sweet oil into the rectum after the fourth day, but of late has changed the oil for warm water; but with exactly what percentage of recoveries I am unable to say. I think, however, the plan has not been altogether successful, as with his last patient, the bowels were constipated for eight days. But this reaching out for something new, and better than the old plan, shows that others besides myself realize that the former custom of constipating the bowels is far from satisfactory.

In Dr. Thomas's last edition (1880) he has described and illustrated this operation in his most admirable manner, and, following the lead of Dr. Granville Bantock, recommends confining the bowels for four days only, until primary adhesion has taken place; then, by the use of enemas and laxatives, to gently move the bowels daily; on the eighth or tenth day removing the sutures, after which the liquid evacuations should be kept up for a week or more, until the parts have become firmly united.

Since this paper was begun, and the statistics of the hospital procured, and my own more carefully studied, I have found in the library of the Academy, the American edition, 1882, of Dr. Arthur D. Eddis, of London, in which, on page 444, he says: "It is, however, unnecessary to keep the bowels confined. The plan of encouraging a daily evacuation by means of oil-enemata has stood the test of experience, and may with safety be recommended." Thus we have one of the latest works recommending, and not condemning, the practicability and the safety of a daily evacuation of the bowels.

Prof. Simon, whose writings have not been so generally read in America as they deserve, taught, both by precept and practice, the advantages of keeping the bowels relaxed after this operation. I am informed by one of his former pupils, that his success was quite remarkable.

I myself, as here related, have found this plan of treatment perfectly safe, far more successful, and attended with the minimum anxiety to the surgeon, labor for the nurse, and suffering to the patient.

Note.—On June 6, 1882, Dr. F. P. Stephens, of this city, requested me to operate on Mrs. ——, of Montclair, N. J. She had placed herself under his care for the relief from the effects of this accident. I found the laceration extending through the perineum and sphincter, but it did not involve the rectum. The Emmet operation was performed; the wires secured as here described. The bowels were moved daily, after the second day, by means of the comp. liquorice powder. The patient ate and drank, and was made entirely comfortable all through her confinement. The sutures were removed on June 16th, ten days after the operation. The result was, and is, a perfect success.

Rickets among the French.—The number of rickety children and hunch-backed adults of both sexes one meets with in France is something prodigious. According to a report lately published in a scientific journal, the number amounts on an average to 20,000 per annum, the female sex furnishing the greatest majority. Want, unwholesome food, and bad hygienic conditions would in a great measure account for these deformities, but the vile practice so prevalent among French mothers of too early hand-feeding their infants, or bringing them up on the bottle to the exclusion of the breast or the milk of an animal, is no doubt one of the principal sources of rickets, and lays the foundation for the malformation of the osseous system, and indeed for the great bulk of diathetic diseases that affect the inhabitants of civilized countries.

It is said that 10,000 infants are sent out from Paris annually to be nursed. Only 3,000 come back alive.

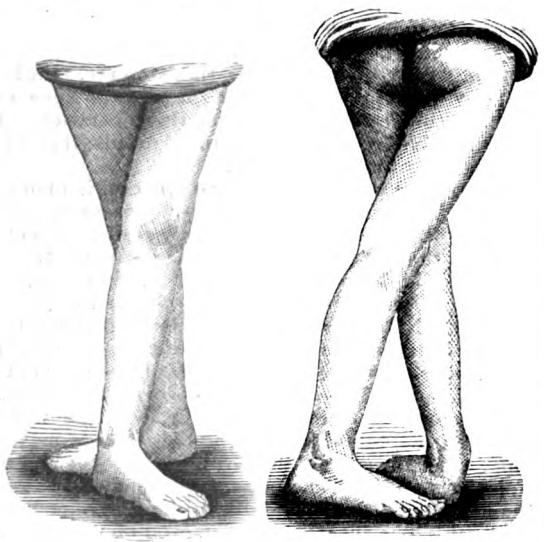
A CASE OF CROSS-LEGGED PROGRESSION.

By CHARLES T. POORE, M.D.,

SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, NEW YORK.

M. T——, aged seven, was admitted into St. Mary's Hospital, April 5, 1881. At time of admission, she was a delicate-looking child, bad teeth, pale.

The following is all the history that can be obtained. She walked well until she was four years of age; at this time she fell on the floor in such a manner that, when found, one limb was behind, "up against her back," her mother states, while the other was straight in front; there is doubt as to which limb was behind, but her mother thinks that it was the left. She suffered much pain in the limb that was thrown back, located in the knee, cried out at night, more especially in damp weather, was under no medical care. She was confined to her bed for some months and then when she began to go about, walked very lame, but no clear account of the manner can be obtained. Some months later,



while on the street, was knocked down and the other limb injured; since then she has been confined to her bed. For some time she has slept sitting up and leaning over a pillow.

On examination it was found that while in bed both limbs were extended and strongly adducted, so that at times they crossed. The right was rotated outward so that the foot laid flat on its outer border and forms with the antero-posterior diameter of the pelvis a right angle. The left limb was also rotated outward, but not to as marked a degree, and could be brought inward to a line nearly parallel with the antero-posterior diameter of the body, while it was impossible to alter the position of the right limb in this direction. The superior border of the trochanter major of both limbs was one inch above Nélaton's line. The right limb is half an inch shorter than the left. There was an elastic swelling two inches below trochanter major on left side. There was some lordosis. There was no swelling, thickening, or tenderness about either hip-joint, except the elastic swelling mentioned above. The fold of the nates was the same on both sides. Motion at the knee joints was normal. Patient complained of no pain either day or night, but resisted any attempt to move the limbs.

During the summer she was out of bed and allowed to go about. It was then noticed that she walked cross-legged, sometimes the right, sometimes the left limb being in front. The limbs were crossed at and a little above the knee. There was also some twisting of the pelvis toward the side on which the limb that was in front.

In June she was placed under ether, and a careful examination made. All movements except those in which the adductors were extended, were smooth and free. No crepitus or roughness of any kind could be detected in the joints. The adductors were strongly contracted and did not relax in the least under ether; it was impossible to overcome the rotation outward of the right limb by the use of any justifiable force.

Patient suffered no ill effects from the examination. She was able after it to flex and extend her limbs.

Hip-joint disease seemed to be excluded. In November she was again placed under ether, and a careful examination made by Dr. George A. Peters, but without throwing any further light on the case. After this last examination she complained of pain in the right knee for a day, but since then was about as before.

December 5th, patient was placed under ether and carefully examined by Drs. George A. Peters, Sands, and Mason.

The following was the result of the examination:

First.—That there was strong contraction of the adductor muscles, and rotation outward of both limbs; the right was rotated to a greater degree than the left and could not be turned inward.

Second.—That both trochanter major were one inch above Nélaton's line.

Third.—That there was shortening of the right limb half an inch.

Fourth.—That there existed a semi-albuminous crepitus in left hip-joint.

Fifth.—It was the expressed opinion that there was an absence of the recognized symptoms of hip-joint disease.

Sixth.—Tenotomy of the adductors of both limbs, as far as was considered safe, was advised.

Tenotomy was accordingly done of as many resisting bands as were not too deep. The limbs could then be abducted to about three-fourths normal abduction, but no change could be made in the rotation outward of the right limb nor any improvement in the left. Patient was placed in bed with her limbs separated.

The wounds healed, and after two weeks she was allowed to get up and go about. She did not walk cross-legged, but locomotion was not improved, rotation outward still continuing. On January 9, 1882, she was placed under ether. No change in the joints can be detected.

The cyst on the outer aspect of left thigh was opened, and considerable caseous matter evacuated. On examining the cavity with the finger it was found to extend upward and inward, so that the finger passed inside the trochanter major. Considerable bony detritus was found in the upper part of the sinus. On crowding the finger inward, the neck, and as much as could be felt of the head of the femur, were found to be extensively diseased.

On February 6th the left hip-joint was excised. The head and neck were only represented by a small spur of bone. The shaft was healthy.

The acetabulum was not increased in any direction, and was only diseased over a small spot in its lower border.

An examination of the part removed shows that the disease is limited by the epiphysis of the trochanter major. Since the operation, pain characteristic of hip-joint disease has developed in the right joint.

There are a few points of interest in this case which I have placed under the following heads:

First.—What was the original injury?

Second.—The cause of the abnormal position of the trochanters.

Third.—The inequality in the length of the limbs.

Fourth.—The cause of the peculiar mode of progression.

First.—There is a question as to which limb was thrown backward; if we assume that it was the right and not the left, may there not have been a rupture of one or both bands of the Y ligament, permitting the limb to fall outward (rotated), and would not continued rest in bed, with the limb in such a position, have resulted in it becoming fixed (rotated outward)?

If the left limb were the one thrown behind, then the position of the right limb can only be accounted for on the supposition that, after the second injury, the joint became diseased and gradually assumed the position it occupies by slow pathological changes taking place in it, and faulty position.

Second.—The position of both trochanters one inch above Nélaton's line. This was due in the left limb to destruction of the head and neck, and not to any dislocation or change in the long diameter of the acetabulum. It would be reasonable to attribute the position of the right trochanter to a similar cause, as that joint is certainly diseased.

Third.—The inequality in the length of the two limbs, the trochanters being on the same plane, can be explained by congenital shortening of the right limb.

Fourth.—What was the cause of the cross-legged progression? There being hip-joint disease on one side, the limb rotated outward and adducted. In order to bring about parallelism of both lower extremities, the pelvis on the diseased side must be raised. Now the other joint becoming diseased, being adducted and rotated outward, and the pelvis tending to assume a horizontal position, a crossing of the limbs becomes a necessity.

There is another explanation that may be given. The right limb being rotated outward and held in this position, the knee-joint could not be used, and was practically anchylosed, as far as any use in locomotion was concerned; this, with contraction of the adductors, would throw the limb beyond and to the opposite side of the median plane of the body; a similar condition of the left, together with the necessity to keep her balance, would cause the peculiar gait found in this case. If one strongly rotates outward both lower limbs and contracts the adductors, he must walk cross-legged. I think that the contraction of the adductors was secondary to the rotation outward; if it had been primary, I think that tenotomy of these muscles would have permitted some correction.

As far as I can ascertain there have been but four cases of this deformity reported, although it is not as uncommon as I at first supposed. In Langenbeck's *Archiv* for 1877 (vol. 21, page 828), is a short report of a case that was treated in Esmarch's clinic. It occurred in a girl twelve years of age, with congenital dislocation of both hip-joints. Her power of locomotion seems to have been better than in any of the other cases.

Mr. Lucas, in the "Transactions of the Clinical Society of London," 1880, reports two cases:

Case II.—A boy aged ten had hip-joint disease on left side when four and one-half years of age; was discharged after some years; went about with a splint; fifteen months later, fell and injured the right thigh. After treatment for some time he was discharged, and six months later was found to walk cross-legged. There was slight motion in the right hip. Both hips had undergone pathological dislocation.

Case III.—Man aged forty-seven; hip-joint disease, left side, of ten years' duration. Nine years later, one year before examination, disease began on the right side. After a time he began to cross his legs; at first was able to unlock them. At time of examination both hip-joints were anchylosed. There was no dislocation.

Case IV.—Mr. Tyson, at a meeting of the Clinical Society of London, April, 1881, presented a patient sixty-seven years of age, who, fifty-three years previous, when fourteen, fell and injured his right hip-joint; was confined to his bed for four months; since then has never been able to go astride a horse. Sixteen years ago he began to have difficulty in walking, his legs becoming more and more approximated; for the last fifteen months he has walked cross-legged. There was only slight motion in the hip-joints; the bone seemed thickened. Both extremities are extremely adducted and everted; heels far apart; toes close together; knees not affected.

Although it is not stated in the text, an examination of the plate in Mr. Lucas's cases shows that the limbs in both cases were everted and strongly adducted. In all these cases there was strong evertion and adduction; in one, there was congenital dislocation of both hips; in one, pathological dislocation; in two, anchylosis, more or less perfect in both joints; while in the case under my own observation the joints are not fixed.

Although it does not come under discussion in this paper, it is worthy of notice how extensive disease there may be in a joint without any positive symptom.

Small-Pox in Birds.—Dr. William Gayton, Medical Superintendent of the Small-Pox Hospital at Homerton, England, writes (*British Medical Journal*) concerning this subject as follows:

"Apropos of 'small-pox in birds,' I may, perhaps, mention the fact that some years ago, a former steward of this hospital was in the habit of breeding a large number of canaries. As these arrived at maturity it was a common occurrence to find many of them dead, and presenting evidence of having suffered from some eruptive disease. It was further observed that, when the hospital contained a somewhat large number of patients, the mortality among the birds increased, and *vice versâ*."

Sudorific Treatment of Typhoid Fever.—Mr. Richard Ryder, praises highly (*British Medical Journal*) the sudorific treatment of typhoid fever, which he has employed for twelve years. He takes incipient cases, and keeps up a continual sweating for eight or ten hours. This is repeated as often as the temperature rises very high. He sweats his patients by covering them with blankets and a macintosh sheet.

SLEEP.

By J. LEONARD CORNING, M.D.,

NEW YORK.

THE physiological factors which are more or less intimately connected with sleep have long been subjects of speculations of a more or less philosophical nature. In recent years, considerable light has been thrown on the nature of those phenomena which are most concerned in the production of that state of the system in which the energies of the various component parts of the organism are more or less reduced. One of the most striking facts to be considered in this connection is the observation that the temperature above the cerebral hemispheres is lower during sleep than during wakefulness. In inverse ratio it has likewise been remarked, that insomnia frequently goes hand-in-hand with a flushed face and heated vertex. When we duly consider these things, there will be found slight matter for surprise that experimenters should have sought to establish the connection subsisting between the sanguineous ebb and flow in the cerebrum on the one hand, and the conditions of sleep and wakefulness on the other.

A priori reasoning on this subject had been indulged in by the older writers on this and kindred physiological themes; indeed, the idea that the brain is in a state of comparative anæmia during sleep has been postulated on purely theoretical grounds by certain physiologists. Only, however, in recent years has actual experimental research contributed somewhat to our more exact knowledge of those factors which are more or less directly concerned in the production of the interesting group of phenomena known as sleep. Of the various writers who have contributed to our knowledge on this subject, there is not one who has done more for our physiological enlightenment respecting the nature of sleep and its accompanying phenomena than Dr. William A. Hammond. And certainly those same phenomena constitute worthy objects for our attention, more particularly when we reflect that about one-third of human existence is passed in sleep.

It was Durham, who, in 1860, demonstrated on dogs the anæmic condition of the brain during sleep. He trephined a piece of the skull, and cementing a watch-glass over the opening, observed that when the animal was awake, the vessels of the pia mater were moderately distended, whereas during natural sleep the brain retracted and presented a pale appearance. The contrast between the aspect of the brain during its functional activity and during its condition of repose is said to have been remarkable.

One of the most lucid expositions of the various questions involved in the consideration of sleep is Dr. William A. Hammond's classical work on "Sleep and its Derangements." I acknowledge my indebtedness to the above monograph for many valuable facts bearing upon the question under consideration. In a monograph of recent date, I have quoted Dr. William A. Hammond's remarkable case of cranial injury, which demonstrated beyond any reasonable doubt the comparatively anæmic condition of the brain during sleep.

Nothing more natural than that after these observations, investigators should have sought to produce sleep by artificially reducing the blood-flow to the brain. Equally to be expected was their selection of the carotids as the arena of their experimental exploits. Simple anatomical considerations would have pointed to these arteries as constituting that portion of the cerebral vascular system at which artificial obstruction could most easily be interposed. The result of experimental compression of these vessels would seem to have sufficiently proven that a diminished blood-supply to the cerebrum induces somnolence.

I have myself produced sleep in this way on numerous occasions (*vide* a short article in THE MEDICAL RECORD for February 18, 1882, and a subsequent monograph entitled "Carotid Compression and Brain Rest," published by Anson D. F. Randolph & Co., New York).

In the above-mentioned communication, the fact that the soporific effects of carotid compression were known to the ancients has been alluded to. But we must not forget that they practised compression on the basis of an empty empiricism, and before the discoveries of modern physiology had elevated medicine from a conglomeration of dexterously formulated ambiguities to the dignity of a progressive science.

The topographical position of the carotid, however, is—for the sake of the logical completeness of the argument, which assumes cerebral anæmia as the proximate cause of sleep—an unfortunate one. Owing, namely, to the contiguity of the artery to the pneumogastric nerve, there are those who affirm that compression of the carotid is only another name for pressure upon the pneumogastric. Now the fact is, that it is much easier to compress the carotid *without* the nerve than to compress the latter without the artery. And I believe there is little doubt that those who thought they were exercising pressure solely upon the nerve were in reality expending their energies upon the artery. The analogy which exists between the physiological effects of ligation and those obtained by compression has been cited by me in former publications as a fact calculated to effectually exclude the theory of pneumogastric agency in the production of soporific phenomena. To be sure, we must not ignore the fact that the effects of ligation are not invariably the same, and that even the effects of compression are subject to a certain amount of variability. These facts may doubtless in a measure be accounted for by the anastomotic variability at the circle of Willis. I am inclined, however, after having used my best efforts to exclude sources of error from my own experiments, and after having examined at considerable length the researches of others in this domain, to find in anæmia of the brain, which term, as a matter of course, includes reduced oxygenation, one of the most prominent factors in the causation of sleep.

As regards the primary impulse, which forms the first link in the chain of physiological events, which culminates in the production of anæmia, I am induced to perceive such a rudimentary behest in the periodic exhaustion of the available intra-ganglionic energy. I am confirmed in this my opinion, that the two great physiological factors of sleep are ganglionic exhaustion and cerebral anæmia, by my own observation that *a certain degree of* compression of the carotids is much more fruitful in the production of soporific effects toward evening than in the early hours of morning. In other words, somnolence by compression of the carotids is more quickly obtained after an expenditure of motor and psychical energy than directly after the brain

has been in a state of repose for a considerable length of time. This fact, I believe, forms the solid basis of an argument in favor of the view that the ganglia are capable, through the benignant influences of rest, of hoarding up a *certain* amount of available explosive energy, which renders them (the ganglia) in a measure independent of the necessity of extensive assimilation from the plastic materials of the blood-stream, at least *for a time*. We must not forget, however, that what we are here considering is a *certain degree* of compression—an amount which, though it would cause somnolence toward evening, would not do so during the hours of early morning, when the central nervous system is in a state of *plastic* rejuvenation. If it be asked what certainty we possess—that, in the instance cited above, the *primary* soporific effects might not be owing to a curtailment of oxygenation, I reply, that in both cases the degree of compression was the same; consequently the amount of oxygen conveyed to the brain was in both instances the same. Consequently the somnolence obtained after psychical or motor activity must have been primarily inaugurated by some change which had taken place within the ganglia during the day—a change equivalent to a condition of *hors de combat* of the intra-ganglionic substance.

Let those who have philosophized about this exhausted condition of the ganglia *call* the phenomenon what they please. Let them talk about cessation of interplasmatic activity, due to the collection of débris within the ganglia or molecular inertia, or anything else, the fact remains the same.

But does what has been said, then, exclude reduction of oxygenation as a causative factor in sleep? Not at all. What I would insist on is simply this: that anæmia, which among other things is equivalent to reduced oxygenation, is, under normal conditions, initiated by intra-ganglionic exhaustion; and that when anæmia, *within certain limits*, is brought about, either through the operation of physiological law or by means of artificial appliances, its effects as a concomitant physiological factor in the production of sleep will be directly in the ratio of the intra-ganglionic exhaustion (always assuming, of course, the absence of irritation within the plasma of the ganglia themselves). I would repeat, when the anæmia is *not carried beyond certain bounds;* for if it so be, either through the agency of perverted physiological law, or by artificial means, a state of unconsciousness may be induced irrespective of ganglionic exhaustion; but this condition has far more in common with what is known as stupor than with *physiological* sleep.

There has been much argumentation as to whether sleep is cerebral anæmia pure and simple, or whether its whole nature is expressed in the term ganglionic exhaustion. Others there are also who, while recognizing in experimental results undeniable proofs of the anæmic condition of the brain during sleep, still persist in perceiving in this anæmia only one of the *collateral* and unimportant effects of ganglionic exhaustion. To corroborate this most gratuitous assumption of the unimportance of the position which anæmia occupies among the causative factors of sleep, they have cited the observation that gourmands frequently sleep after enormous meals, their red and swollen features meanwhile bearing ample witness to the condition of cerebral hyperæmia. They forget, however, that there is a vast difference between the condition of partial *stupor*, engendered by such causes, and the healthy *physiological sleep* which the laborer enjoys after a day of toil. The truth of the matter seems to be that the term sleep, when employed to designate more particularly a condition of rest of the central nervous system, means, physiologically considered, a similar condition of things to that which prevails during inactivity in certain tissues, which are subject to periodical exacerbation and diminution of function, as, for example, the glands. The temperature in these structures is found to be much lower during rest than during functional activity. It has also been observed that the temperature of muscles is higher during activity than during rest. Now a rise in temperature, among other things, means the conveyance of an increased amount of oxygen to the tissues within a given length of time, or, in other words, a condition of physiological hyperæmia. Inversely, rest takes place in the tissues as a co-sequence of reduced oxygenation and intra-plasmatic exhaustion. Strikingly suggestive as these analogies are in themselves, there are, moreover, the *direct* proofs of the exceptionally dependent condition of the brain on the good offices of the blood-stream, as seen in the remarkable phenomena induced by cerebral hyperæmia and cerebral anæmia. Sleep, therefore, may be considered as the sum of the phenomena expressed in general terms by the designations cerebral anæmia *and* intra-ganglionic exhaustion.

If it be asked: Wherein lies the practical utility of such considerations as the foregoing? the reply, pure and simple, is this: That for the proper understanding and treatment of that great curse of a relentless civilization—insomnia—a proper understanding of the physiological requisites of *natural* sleep is an indispensable necessity.

Skin-grafting from Rabbits.—Dr. Lamallerée, of Paris, several months ago, performed an operation of skin-grafting, employing grafts obtained from two different sources, a human being and a rabbit, those from the latter evincing a superior amount of vitality. The patient, a man thirty-seven years old, had suffered for six years from a varicose ulcer of the left thigh, which resisted every form of treatment. The ulcer was 14 centimetres long and 8 deep. At the request of the patient, Dr. Lamallerée determined upon skin-grafting, for which he obtained six grafts from the abdomen of a rabbit, it having been previously shaved, and two from the forearm of a man. These having been placed in position, a Lister dressing was applied. After the lapse of eight days, this was removed, and it was found that those furnished by the rabbit had become adherent, and that new skin was forming rapidly in their immediate neighborhood. On the other hand, the two which had been taken from the man had not adhered. The dressing was continued eight days longer. When it was removed, an islet of skin, 10 centimetres long and 7 wide, was seen to have established itself upon the centre of the ulcer. The dressing was again reapplied, and maintained *in situ* for eight days, at the completion of which it was taken off, and it was found that the sore had completely cicatrized. Two months later the patient was again seen, the healing process was progressing favorably, and the newly formed skin showed no trace of its origin.—Dr. E. C. Vidal, in *Monthly Review of Med.*

The London Pathological Society is so overrun with specimens that special meetings are necessary to consider them.

Progress of Medical Science.

FATAL POISONING WITH CHLORATE OF POTASSIUM.—Dr. Lingen publishes in the *St. Petersburger Medicinische Wochenschrift* (March 6 1882), the history of a fatal case of poisoning from the immoderate use of chlorate of potassium. The quantity of the drug ingested was not accurately ascertained, but it probably amounted to several ounces. The initial toxic symptoms were thoracic oppression, tremor, repeated vomiting, diarrhœa, restlessness, gastric pain and asthenia. The patient lived a week after the first appearance of the symptoms. During this time asthenia became gradually more marked. The urine was dark-red, notably diminished, and contained a large quantity of albumen with blood casts, disintegrated blood corpuscles, renal epithelium, and granular detritus. Vomiting occurred from time to time. Death from asthenia. No autopsy was held. Dr. Lingen supplements the history of his case by quoting the pathological conditions observed by Marchaud in a series of fatal cases of potassium chlorate poisoning. The blood was of a pure brown chocolate color; the kidneys were enlarged; the urinary tubules in the medullæ were distended with peculiar granular, brownish casts, containing disintegrated blood corpuscles. Dr. Lingen concludes, however, that chlorate of potassium may be safely employed internally, in doses amounting to one drachm per diem.

SIMULTANEOUS OCCLUSION OF BOTH URETERS BY RENAL CALCULI: DEATH AFTER ANURIA OF FIVE DAYS' DURATION WITHOUT URÆMIA.—Dr. H. Haehner published in the *Berliner Klinische Wochenschrift* for September 12, 1881, an elaborate history of a case, the main features of which are indicated by the above title, together with a report of the autopsy. The patient was a previously healthy man, aged fifty-one years. On October 20, 1881, he engaged in more active physical exertion than usual, and shortly afterward observed a clot of blood in his urine. He had not received any injury. The expulsion of the coagulum was unattended by pain. On the two following days the patient passed an unusually small quantity of urine and suffered from slight rectal tenesmus and fever tympanites. During the night of October 22d, severe paroxysmal pain was developed in the hypogastric and lumbar regions and radiated into the testicles.

The pains continued to recur at intervals, and the urine which contained a few coagula, to diminish in quantity until complete anuria became established on October 25th. From that time until the patient's death, on October 30th, no urine was voided and none reached the bladder. Tumors developed in the lumbar region, corresponding to the location of the kidneys, and intense pain continued. Diaphoresis and catharsis were artificially induced. There was slight delirium but no marked uræmic symptoms were noted.

The tumor in the right lumbar region was punctured on October 30th, and 100 grammes (3 ounces) of clear, acid fluid, which responded to the murexide test, but had no urinous odor, were withdrawn. The general condition was unchanged by the operation; dyspnœa appeared and developed into orthopnœa. Death from asthenia and dyspnœa occurred on October 30th. The autopsy showed complete occlusion of both ureters by calculi, varying in size from that of a lentil to that of a pea. Similar ones were impacted in the pelvis and in the calices, and the intervals between them were closely packed with gravel. None of the calculi were of such large dimensions that they might not have singly passed through the ureters, but they were firmly wedged into the latter and cemented together by the finer calculous particles. Both kidneys were immensely dilated. The mucous membrane of the pelvis was ulcerated and ecchymotic. Dr. Haehner supposed that the unusual exertions of the patient just before his attack caused the descent of the calculi from the pelvis and their impaction in the ureters. The absence of uræmic phenomena was attributed by him to the copious evacuations and the abundant diaphoresis induced by remedies.

THE CLINICAL SIGNIFICANCE OF RETRACTILITY OF ALBUMEN.—Dr. Rodet devotes an article in the *Lyon Médical* for April 23, 1882, to a refutation of Professor Bouchard's views relating to the possibility of distinguishing the albuminuria of renal disease from that complicating various other pathological conditions. Professor Bouchard believed that he had discovered a distinctive physical condition characteristic of albumen present in urine as the result of nephritis. This was a so-called retractility on the part of the albumen, manifested by its assumption of a form distinctly seen with the naked eye to be flocculent. Flocculent or retractile albumen was, according to his view, normal serum albumen, which could only be present in the urine in virtue of some renal disease. Non-retractile albumen, or albumen which presented a homogeneous, whitish aspect on coagulation, was, on the other hand, abnormal albumen, capable of penetrating normal renal epithelium by dialysis. Dr. Rodet subverts Professor Bouchard's theory by showing that the two forms of albumen in question owe their peculiar character to the chemical nature of the coagulating reagent. "Retractile" albumen appears when acetic acid is added to the urine before precipitation of the albumen, and non-retractile or homogeneous albumen when an alkali has been previously added. Dr. Rodet also calls attention to the fact that even the coagulated albumen of homogeneous appearance consists, in reality, of flocculi too minute to be detected by the naked eye.

PHTHISIS PULMONALIS ENDING IN RECOVERY OR IN ARREST OF THE DISEASE.—Dr. Francis Minot, Physician to the Massachusetts General Hospital, publishes the history of seven cases of pulmonary consumption in the *Boston Medical and Surgical Journal* for May 4, 1882. Three of them may be considered as examples of recovery. One of them was, however, followed, after ten years, by a fatal recurrence of the disease. In the first case which recovered there were, for several months, conclusive physical evidence of phthisis at the apex of the right lung. Two years later all signs of the disease had disappeared, and the patient's general health was excellent. Another case was characterized by well-marked symptoms and signs of phthisis. This patient's improvement was rapid and his recovery apparently complete. After eleven years he died of a cardiac affection. In the third case of recovery a recurrence took place after ten years and proved fatal six months later. The treatment was conducted in accordance with generally accepted principles. The patients were enjoined to remain as much as possible in the open air, except on stormy days; never to remain in rooms warmed by furnace heat unless there

were also an open grate fire; always to sleep at night with a window partly open; to take a daily sponge-bath, not so cold as to occasion chilliness; to wear suitable woollen underclothing, both summer and winter; and to fully inflate the lungs at regular intervals throughout the day, in order to stimulate the pulmonary circulation, especially that of the apices.

LICHEN PLANUS AFFECTING THE MUCOUS MEMBRANE.—At a meeting of the Medical Society, of London, March 27, 1882, Dr. Radcliffe Crocker presented a case of lichen planus affecting the mucous membrane as well as the skin, furnishing also the history of two other cases. On the skin and glans penis, in the case presented, the usual characteristics of the disease were present, but upon each side of the raphé of the tongue symmetrical white patches were found, and the buccal mucous membrane exhibited white streaks extending from the parts adjacent to the last molar teeth to the lips. In the other cases the mucous membrane of the cheeks presented similar characters, but the tongue was affected on the sides only. The point of interest was that the lesion of the mucous membrane preceded those of the skin by some weeks, in at least one instance. Mr. Hutchinson is said to have been the first to notice these white patches in connection with lichen planus. Though occurring only in a certain number of cases, when present the symmetry of the patches on the tongue and fern-like branching of the white streaks were the points specially noticed. The possibility of their preceding the skin lesions gave them importance from a diagnostic point of view.—*The Lancet*, London, Eng., April 8, 1882.

A DISEASE OF THE MAMMARY AREOLA PRECEDING CANCER OF THE BREAST: PAGET'S DISEASE.—Dr. C. B. Porter, Surgeon to the Massachusetts General Hospital, publishes an interesting article (embodying the description of a case) upon the above subject, in the *Boston Medical and Surgical Journal* for May 4, 1882.

Sir James Paget first described the disease in question in the *St. Bartholomew's Hospital Reports* for 1874, having observed fifteen cases up to that time. The patients were all women, from forty to sixty years of age. In all the cases the disease began as an eruption on the nipple and on the areola. It usually had the appearance of a florid, raw, finely granular surface, from which the epidermis seemed to be absent. A greater part, or the whole of the nipple and of the areola was usually involved. A copious, clear, yellowish and viscid exudation flowed from the diseased surface, which was the seat of tingling, itching, and burning sensations. The general health remained good. The eruption did not extend beyond the areola, nor did it produce subcutaneous ulceration in Paget's cases. It resembled either chronic eczema or psoriasis. In the latter form it was observed to extend beyond the areola, in a few cases. In all those studied by Paget, cancer of the breast followed the eruption after an interval usually of one year, but in certain instances of two years. The cutaneous disease resisted all treatment, both local and general, and continued even after the appearance of genuine carcinoma. The cancer was never first developed in the diseased skin, but in the mammary parenchyma, beneath or not far from the diseased cuticle, and was always separated from the latter by an interval of apparently healthy tissue. The cancers were mostly of the scirrhus variety, recurred after extirpation, and terminated in death. The case described by Dr. Porter occurred in the person of a woman aged fifty years. Two years before she came under Dr. Porter's observation, she noticed "three little pimples, like water blisters," near the right nipple. They caused neither pain nor inconvenience. They soon discharged, causing adhesion of the garments to their surface, and were followed by the eruption of new vesicles. After nine months, sharp pains were felt in the nipple and breast. Two years after the appearance of the disease the areola and its immediate neighborhood were involved in the disease, which presented essentially the same characters as those described by Sir James Paget. The eruption was dry and scaly in parts, and consisted of soft, moist scabs in others. The surface beneath the scales and scabs was raw, red, and granular. Around the edge of the scaly patches were minute vesicles, some of them covered with small dry crusts. The breast also presented the typical signs of cancer. It was, therefore, removed, the wound healed by first intention, and no recurrence had been observed after a year. On examination of the breast, the nipple was found destroyed by a cancerous growth of the epithelial type. In some of the milk-ducts there was an abnormal growth of epithelium, which had led to carcinomatous infiltration of the glandular parenchyma. Mr. Butlin has reported two similar cases, from the study of which he reached the following conclusions: (1) A certain relation existed between the eczema of the nipple and areola and the carcinoma of the breast. (2) One of the first effects of eczema was to produce proliferation of the mucous layer of the affected epidermis. (3) In the course of time the epithelium of the galactopherous ducts became similarly affected. (4) The disease gradually involved the smaller ducts, then the acini, and, finally, the parenchyma. (5) The carcinoma thus developed was essentially epithelial in character.

Dr. Thin applies the term "Malignant Papillary Dermatitis" to this cutaneous affection, which has also been described by Dr. S. W. Gross, in his work on "Tumors of the Mammary Gland."

THE EPITHELIA OF THE KIDNEY.—In the June number of the *New York Medical Journal and Obstetrical Review*, Dr. Henry B. Millard gives an account of his researches in the anatomy of the renal epithelia, and thus sums up the results: 1. The rods discovered by Heidenhain in some varieties of the tubuli uriniferi are part and parcel of a reticulum present within every epithelium. 2. The reticulum, including its elongated rod-like or sheath-like formations, is the living matter proper. 3. The relation of the rods to the rest of the reticulum of an epithelial body varies greatly, the variation probably being due to different stages or degrees of secretion. 4. The reticulum, including the rod-like formations, in the inflammatory process, both in catarrhal and in croupous nephritis, gives rise to a new formation of living matter, which results in the new formation of medullary corpuscles or pus corpuscles. 5. The structureless membrane is lined by flat endothelia lying between it and the basis of the epithelia of the urinary tubules. 6. In nephritis the endothelia become considerably enlarged, and, in catarrhal as well as in croupous nephritis, they line the urinary tubules after the epithelia have been shed or lost; they surround the cast in croupous nephritis after the epithelia have perished in the formation of the cast.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, July 1, 1882.

CONTAGIOUS EYE DISEASES IN SCHOOLS AND ASYLUMS.

We are so often assured of the great interest taken by the profession on all matters pertaining to the proper sanitary regulations of public schools, that we are encouraged to continue the discussion of the subject by presenting such facts and conclusions bearing upon it, as may from time to time be presented from different points of observation. We have so often commended the efforts of the State Board of Health of New York in diffusing useful knowledge on all questions relating to public health, and particularly to school hygiene, that it is almost useless to say that a recent tract on "Contagious Diseases of the Eyes in Schools and Asylums," by Dr. C. R. Agnew, of this city, published under its auspices, is a timely and instructive document. Dr. Agnew points out, in a forcible and direct manner, the prevalence of communicable eye disease as one of the many evils which exist in the method of treating children upon the congregate plan in schools and reformatories. Some time ago he was called to a school, in one of the counties of this State, in which several hundred children had been gathered, chiefly from the streets of the city, and found more than half the inmates, one hundred and fifty in number, suffering from a malignant type of purulent ophthalmia. The disease had proceeded so far that several cases of blindness had already occurred, both among the scholars and their attendants, five children having lost both eyes, and seventeen children having each lost an eye. It was safely estimated that at least five per centum of these pupils would become blind in one or both eyes, and that a considerable number, probably one-half, would have such morbid changes produced in the conjunctiva as would render them liable to constantly recurring ophthalmia.

When it is considered that, with proper sanitary regulations, such a widespread and damaging epidemic could have been prevented, the picture is a saddening one in the extreme, and reflects seriously upon any system of management which makes such a condition of affairs possible. It is hardly necessary to say that the mere presence of such a disease in any school or reformatory is severely censurable, as showing a want of knowledge of the most ordinary rules of sanitation. Hence, we are not surprised to learn that there was no care whatsoever exercised in quarantining the sick ones, no measures taken for proper examination of the eyes before admission; that the lavatories were insufficient, the food and drainage were bad, and the institution was overcrowded. And here comes in the old argument for competent medical inspection of all institutions in which children are congregated, either for purposes of education or physical training, or both.

In fact, until such is accomplished, we shall continue to have the experiences, as are recounted by our distinguished ophthalmologist, constantly repeated.

There is, however, even a melancholy satisfaction in all this. The public need to be educated to the importance of the measures advocated, and no more effectual means to such an end can be instituted than by the constant reiteration of the principles which underlie the prevention of contagion, and the removal of the causes of crowd poisoning.

In this little history of communicable eye diseases, we have illustrated all the usual effects of neglect of quarantine, insufficient ventilation, defective lavatories, imperfect sewerage, and bad food. Perhaps the whole matter could not be more effectually placed in a nutshell than by quoting the following extract from a letter written to Dr. Agnew by a physician recently appointed to one of these reformatories, detailing the results of his first medical inspection:

"A strong odor of sewer gas pervaded the building, which proceeded from several foul and entirely unventilated pan water-closets, the soil pipe from which emptied by means of a leaking sewer, which was also without trap or ventilator, into an adjoining privy vault, the discharge being entirely below the water line. No fresh air was admitted to the soil-pipe or sewer. The kitchen and laundry waste was discharged upon the surface of the ground, *the latter under its floor*. The institution contained three hundred and eight children, crowded together in close, unventilated rooms, sunlight and air being rigidly excluded. In one sleeping apartment *above* the laundry these children were placed two and three in a bed, with *less* than *one hundred and twenty-five* cubic feet of air apiece, the windows and blinds being closed. Fortunately no water-closets had been placed here, but two tin slop pails, placed in the centre of the room, were used instead. The food was of poor quality. I believe but ten quarts of milk were furnished daily. Two troughs, sixteen

feet in length, answered for a lavatory, all washing in the same water, while the few towels in use were employed indiscriminately. Sore heads were almost universal, dependent principally on the vermin inhabiting them. The itch was also very prevalent. I subsequently learned that several children had died from *cerebro-spinal meningitis*. Forty-eight children and attendants were suffering from fully developed purulent conjunctivitis. Perforation of one cornea had already taken place in three cases, of both cornea in one case. *Six cases had been removed to hospital. Of these*, three lost both eyes. Three lost one eye, each. The disease had prevailed the preceding year, just how extensively, I was unable to ascertain; but the institution still contained five children who had lost both eyes, and seventeen who had lost one, each, at that time.

"*Of the remaining children scarcely one could be said to possess a healthy conjunctiva.*"

The question now comes up, as to what can be done to remedy such evils, aside from enforced sanitary inspection. Obviously, the State is competent to fix some standard of requirements, which shall be uniform and binding upon all public schools and reformatories. This should certainly be advised by our State board. The following suggestions of Dr. Agnew look in the proper direction of initiating the necessary reforms, and will doubtless shape some of the recommendations soon to be offered by the health authorities.

He believes that schools and reformatories should be licensed by the State, under a general law like that, for instance, determining the capacity of emigrant ships, so that overcrowding and bad food would be impossible without a misdemeanor on the part of their managers. The license should state in terms what cubic air space must be secured for each inmate and what the dietary must be. Then no school or reformatory would have more inmates than the building should contain or its resources properly maintain, and societies for inquiry and advice would have some definite duties to perform with reference to them. The law should fix a minimum of eight hundred or one thousand cubic feet of air space for every such inmate, and at least one quart and a half of good milk, of definite purity, besides other specified food for each inmate, and also determine methods of applying the principles for drainage and ventilation and out-of-door work and amusements.

THE RADICAL CURE OF CANCER.

The most recent utterances regarding the possibility of radically curing cancer have been of a hopeful character. While the pathology of the disease is not positively and completely known, yet the tendency of later researches is not unfavorable to the view that there may in time be some kind of specific for it discovered. Epitheliomata and even the more malignant forms are cured by the knife in a few cases. There is very good evidence that by internal medication uterine cancer in its early stages has been checked, if not permanently removed.

Coming at this time, therefore, when the horizon is brightening a little, the stimulus of so large a prize as that offered through Dr. J. Collins Warren, of Boston, Mass., ought to secure something of value. It should be remembered that the prize is not necessarily for a specific remedy for cancer, but for the best essay upon the probability of the discovery of a cure of the malignant disease, and the line of study or experimentation likely to bring such a cure to light.

There is an assured position and reputation to the person who can worthily win a prize on so important a subject. We trust that it will be widely competed for.

THE LAST OF GUITEAU.

The petition for a respite to Guiteau was refused, and the assassin will have met his fate before this writing appears.

There is but little more to be said now of the case. It has already excited vastly more attention than it deserved. Guiteau, and all Guiteaus should, in the present stage of society, be considered responsible, and should be punished. The protection of society and the demands of justice alike call for it.

There has been much said of late about "the best leading experts," and how sure they are that Guiteau is insane. These experts are quite entitled to their opinion, but it is a mistake to suppose that they represent all the best and widest experience in psychiatry. That in the future Guiteau will be considered insane and irresponsible we cannot believe, assuming that futurity will interest itself in the assassin at all.

Guiteau was the victim of a peculiar psychosis. He was not sane, but we hold that future jurists and experts will find themselves in trouble if they class this psychosis strictly among the insanities. The difficulty that will arise has already shown itself. The insane man cannot do a criminal action; he is not and cannot be criminally responsible. This truth has rarely been questioned. Yet society cannot and will not tolerate the idea that so-called "reasoning maniacs," of the Guiteau type, are irresponsible and require no punishment. Difficulties, disputes, injustice, even social danger, will arise if an original moral perverseness, developed by self-indulgence, makes a man a lunatic, incapable of crime.

Moral insanity has been the bane of the code, and it will continue to be as long as experts insist that Guiteaus are irresponsible. There is such a thing as ultra-expertness, as too much specialism. It sees an uncanny light in every eye. Its psychology deserves to be written.

THE MALLEY TRIAL.

THE Malley trial, which will have closed, we presume, before this appears, has attracted a great deal of morbid interest. Two young men, no worse than society often receives; two women, no worse than the men; dissipation, adultery, and a mysterious death; these are the elements of the story.

But apart from its tragic interest or repulsiveness are some medico-legal problems of a very puzzling character.

The young woman, Jennie Cramer, was, it is claimed, seen alive and well at 11 P.M. Friday. Next morning at 5 A.M. her body was found floating near the beach. It was taken to the undertaker, and two days later a post-mortem was made. Mucous froth and a little sand were found in the trachea. The lungs were normal; there was about half a pint of reddish fluid in each pleural cavity; the stomach was healthy and contained the remnants of a meal. The other organs were normal, except that the brain was somewhat congested. Subsequent examination showed that there was in the whole body $3\frac{1}{10}$ grains of arsenic, distributed through almost all the tissues, except the bones; not quite one-sixth (.46 grain) being in the stomach and intestines.

The question is, was death produced by the arsenic or by drowning? It is a most difficult one to answer. The self-confidence of the young experts who said or swore that the arsenic killed her, is a curious illustration of the mental bias which comes from knowing too much of one thing. Dr. Beach, of this city, seemed to be the only one who really appeared to appreciate that the case was not a simple one.

There are no signs of drowning which are pathognomonic. It was perfectly possible that death might have occurred in that way. On the other hand, death might have been produced by the arsenic. But that three grains should have been given within five hours, without producing any gastro-intestinal irritation, without even causing vomiting, makes the arsenic theory a difficult one to defend. It is not at all impossible that the girl had been in the habit of using arsenic. Although the drug is usually soon eliminated, this is not always the case. And it cannot be said positively that the amount and distribution of arsenic in the body was not such as might be found in persons who are daily taking it. We repeat, therefore, here what we said some time ago, that it would be unjust and monstrous to hang a person upon the too expert evidence in favor of the arsenic theory.

THE BURNING OF THE INTERNATIONAL HYGIENIC EXHIBITION BUILDING.

THERE is very wide-spread regret at the burning last month of the building, with its contents, erected for the International Hygienic Exhibition in Berlin. A great deal of money, as well as of hard work and anxious thought, had been expended in efforts to make the exhibition a success. In a few minutes everything was destroyed. Rarely has an enterprise with so much of promise to science and human life received such a complete check.

Great efforts are making to prevent the exhibition from failing entirely. It will hardly be possible, it is said, to open the rebuilt structure this year, but it will be delayed as short a time as possible. There is plenty of pluck among the managers, and money is not deficient. The Empress of Germany has also had twenty gold medals struck off for the occasion. The trouble will be with exhibitors. These have already expended money on goods which have been destroyed by fire, constituting, in most cases, a direct loss with no compensation. It seems, however, that if confidence is secured in the still prospective exhibition, goods can easily be obtained. At least every one will now feel an additional interest in the exhibition that has been so dolefully advertised by the flames. By a little more hard work it can be made more successful than was ever anticipated.

THE DECLINE AND FALL OF THE AMERICAN MEDICAL COLLEGE ASSOCIATION.

THE American Medical College Association held its annual meeting in Cincinnati recently. It voted to rescind the resolution making a three year course obligatory upon its members.

Thus ends this once hopeful offspring of reformatory aspirations. Its body may go marching on, but its soul has melted into the infinite azure of the past—at Cincinnati. We should, perhaps, express our sorrow; but it was always a strumous boy.

So it may be as well that the association does not prolong an existence which has not for some time been a healthy one. We are truly sorry for those few concerned who really wished educational reform. But the time was not ripe. The trade in medical students calls out active competition, and demands the best business ability. One cannot sell high when his neighbor sells low. We must wait until the profession and public demand only the best goods.

It seems a little hard, to be sure, that the attempt to secure reform should be such a rapid and complete failure. Our profession has a Code of Ethics, and is presumably guided by higher than merely business instincts. But none of the many colleges in the association were willing to risk a little loss of money by advancing their standard. Yet many of these our brethren have shown great capacity for moral feeling in belaboring the New York Society.

If there could only be awakened the same tremendous zeal against the abuses of medical education, so deep-rooted and pernicious, that has been shown toward our State society, there would be true cause for congratulation.

Reviews and Notices of Books.

LEHRBUCH DER HYGIENISCHEN UNTERSUCHUNGSMETHODEN. EINE ANLEITUNG ZUR ANSTELLUNG HYGIENISCHER UNTERSUCHUNGEN UND ZUR BEGUTACHTUNG HYGIENISCHER FRAGEN FÜR AERZTE UND CHEMIKER, SANITÄTS- UND VERWALTUNGSBEAMTE, SOWIE STUDIRENDE. Von DR. MED. C. FLÜGGE, Privatdocent an der Universität Berlin. Mit 88 Abbildungen im Text, 17 Tabellen, und 4 Lithographirten Tafeln. 8vo, pp. viii., 602. Leipzig: Verlag von Veit & Comp. 1881.

Text-book of Hygienic Examinations. A Guide-Book in all Matters relating to Hygiene, for the Use of Physicians, Chemists, Sanitary and Government Officials, and Students. By DR. C. FLÜGGE, Privatdocent at the University of Berlin. With 88 Woodcuts, 17 Tables, and 4 Lithographic plates.

To those interested in questions of hygiene, this book will supply a keenly felt want. Characterized by German thoroughness, it covers the whole field of the broad subject of the methods of hygienic examinations. What was formerly scattered over an immense range of literature is here condensed and brought together in one volume, at the same time being supplemented by extensive original observations of the author. The work in its six subdivisions considers the various modes of examination for all the surroundings of man which have an influence upon his health, each chapter concluding with a critical consideration of the matters discussed. The most important and most frequently executed methods are, as far as possible, detailed in such a manner as to be understood without special knowledge of analytical chemistry on the part of the reader. Unsolved hygienic problems and disputed points are considered only when bearing upon the methods described. The antagonistic views in regard to ferments, however, are treated of at some length, on account of the great practical importance of this part of the subject.

The book, as already stated, contains six sections, viz.: I., Examinations of the Air; II., Of the Ground; III., Of Water; IV., Of Food; V., Examinations of Ferments, Micro-Organisms, and Disinfectants; VI., Examinations of the Special Surroundings of Man. In his chapter on Ozone, after considering the differential tests of this gas, which serve to distinguish it from bromine, chlorine, hydrogen peroxide, and nitrous acid, the author details the various processes for its quantitative determination. In spite of the efforts of many experimenters, he says, a satisfactory method of ozonometry has not yet been determined. The reason why faulty procedures have been so minutely described is founded on the exaggerated views held by some in regard to the hygienic significance of ozone. Such views must, of course, be based upon experimental researches involving quantitative analyses. If the latter be faulty, then these theories will, of course, lack foundation. Even if they be not altogether valueless, yet they offer no indications as to the hygienic significance of ozone. At certain meteorological stations, twenty years of observations have simply shown that the percentage of ozone is increased during the prevalence of strong winds and frequent rainfalls. In certain localities a minimum percentage occurs during November and July; in others, a minimum occurs in September, and a maximum in February. No parallelism with the prevalence of infectious epidemics can be established. Experiments upon animals demonstrate the toxic properties of the gas. It is never found in dwellings, on account of the presence of organic substances which destroy it, nor is there any proof that disease-germs have a greater affinity for ozone than other organic material found in the surroundings of man. The ozonometric papers, now in use, says the author, are to be discarded, except in so far as they are used as qualitative reagents. He hopes that meteorological stations will abandon a method which results in no gain to science, but rather serves as a stimulus to groundless speculations.

Altogether, this volume is the best of its kind which has hitherto appeared in any language. It is a work, however, that must be carefully studied before any practical benefit can be derived from it. A hasty glance at its contents will only confuse the physician in search of reliable information on matters relating to hygiene.

DIE ANWENDUNG DER ELECTRICITÄT IN DER PRAKTISCHEN MEDICIN. Von DR. B. A. ERDMANN, Königl. Sächs. Med. Rath, etc., Vierte Auflage. Mit 72 Holschnitten. Leipzig: Joh. Ambrosius Barth. The Use of Electricity in Medicine. By Dr. B. A. ERDMANN.

THE fourth edition of Dr. Erdmann's practical volume on medical electricity, although published a few years ago, is in all essential respects a modern treatise. It has this in its favor, that it is evidently written by a man thoroughly conversant with the best modes of applying the different kinds of electricity so as to produce the most satisfactory curative or palliative results. A great personal experience, extending over many years, enables Erdmann to speak with considerable authority on all empirical facts connected with the daily therapeutical use of electricity. That the author has not fallen into the common error of enthusiastic specialists in exaggerating the true value of their respective modes of treatment, is a circumstance which goes far to establish the reader's confidence in his assertions. The judicious moderation of his claims vouchsafes the author's honesty of conviction and purpose. The whole subject is dealt with in the becoming spirit of a searcher after scientific truth. At the same time, however, the fact is duly recognized that in electrology, as in numerous other matters relating to therapeutics, practical empiricism is greatly in advance of actual scientific knowledge. Accordingly, we find throughout the book the evidences of an analytical mind, which has applied itself to the solution of scientific problems, without any neglect of the practical lessons taught by every-day experience. It is this feature of the book which makes it a desirable and valuable acquisition both to the student and novice in electrology and the working practitioner. The latter will be especially pleased by the many eminently practical suggestions and valuable hints scattered through the pages of this treatise. The illustrations accompanying the text are fairly done. They are amply sufficient to elucidate certain necessary points, without converting the book into a picture gallery of instrument makers' manifold traps and contrivances.

TRANSACTIONS OF THE ILLINOIS STATE MEDICAL SOCIETY. Chicago, 1881.

THE contents of this volume are of unusual interest. The "Committee on Practical Medicine" report very fully on the diseases, and the changes in type

and treatment therein, of the last year. The article on the "Uses and Abuses of Alcohol," is an important one, as this is a subject upon which special legislation is at fault. All the communications are good, each one presenting points for consideration. The book is neat in appearance and has excellent paper and print.

REFRACTION OF THE EYE. By A. STANFORD MORTON, M.D., London.

THIS little book was prepared for the purpose of enabling practitioners to diagnose, and estimate the value of the phenomena indicating the state of a patient's refraction. It furnishes a basis for observation, in the effort to acquire proficiency in prescribing correct glasses.

THE HARROGATE WATERS. By G. OLIVER, M.D., London.

IN sketching the medical aspects of this watering-place, for the guidance of the profession in the selection of cases, the author has endeavored to provide reliable data on (1) the climate of Harrogate viewed as a health resort; (2) the mineral waters—the latest recorded views and facts as to their constitution, and their therapeutic range and powers.

A POCKET-BOOK OF PHYSICAL DIAGNOSIS FOR THE STUDENT AND PHYSICIAN. By Dr. EDWARD T. BRUEN. Philadelphia: Presley & Blakiston. 1881.

MANY able works upon physical diagnosis having been published of late years, among which may be mentioned those of Delafield, Flint, and Loomis, the *raison d'être* of the present volume is not perfectly apparent. It does not, nor could it justly lay claim to originality either of method or of matter. Its style is so rhetorical as often to be obscure. Its earlier chapters are devoted to a general discussion of the familiar methods of physical diagnosis. Diseases of the lungs and heart are subsequently treated of in detail, with special reference to their physical signs. Diseases of the abdomen are not considered.

SYMPATHETIC DISEASES OF THE EYE. By LUDWIG MAUTHNER, M.D., Vienna.

THE author, in presenting this comprehensive monograph, has two objects in view: one to compile for ophthalmic surgeons the widely diverse opinions on the subjects under discussion; the other, to enable the general practitioner and student in ophthalmology, to gain an insight into the pathology and treatment of the more important diseases of the eye.

MARRIAGE AND PARENTAGE. 12mo, pp. 170. Published by the author, M. L. HOLBROOK. 1882.

THIS little book consists essentially of a reiteration of many trite facts and statistics relating to parentage, and the transmission of traits of character as well as physical infirmities. It contains, however, many good suggestions, particularly in the chapter headed "Sanitary Parentage."

The author's very laudable ambition is to promote a gradual, healthy growth of ethical and physical power in the human race. To this end he lays great stress on the physical fitness of an alliance, but omits to consider that great factor in human happiness—sentiment.

THE SMALL FEE SYSTEM has been abandoned at the out-patient department of the Massachusetts General Hospital. In this city it is in favor still, because it brings in a considerable sum to the treasury. Whether it helps to correct abuses in medical charity is doubtful.

Reports of Societies.

AMERICAN NEUROLOGICAL ASSOCIATION.

Eighth Annual Meeting, held in New York, June 21, 22, and 23, 1882.

WEDNESDAY, JUNE 21—FIRST DAY, AFTERNOON SESSION.

THE Association met in the hall of the Academy of Medicine, and was called to order at 2.30 P.M. by the Secretary, DR. E. C. SEGUIN, of New York, who introduced the President, DR. WM. A. HAMMOND, of New York.

The President congratulated the members on the positive, unequivocal, and permanent success of the association. Nowhere in the world had neurological science been more sedulously cultivated than in this country. The measure which he especially commended was the propriety of establishing local neurological societies, which, in the end, would be feeders of this association.

After the reading of the official reports, DR. C. L. DANA, of New York, was nominated for membership.

NOMINATION AND ELECTION OF OFFICERS

being next in order, Dr. R. T. EDES, of Boston, was elected President; DR. W. J. MORTON, of New York, Vice-President; DR. E. C. SEGUIN, of New York, Secretary and Treasurer; and Drs. F. T. Miles, of Baltimore, and J. C. Shaw, of Brooklyn, Members of the Council.

The place for holding the next annual meeting was referred to the Council, with power.

An amendment to the constitution was adopted, which provides that "members removing from within the limits of the United States shall thereby become associate members, if they so desire."

The Committee on

THE HAMMOND PRIZE

of $500, offered for the best essay "On the Functions of the Optic Thalamus of Man," reported that only one essay had been submitted, which, however, did not contain any really original material, and did not advance our knowledge of the thalamus, and therefore was not entitled to the prize.

DR. HAMMOND renewed the offer for another year, and said that if at the end of that time no essay was received worthy of the prize he would give the money either to the association or to the New York Neurological Society as a nucleus for a prize fund.

The committee, Drs. Miles, of Baltimore, Jewell, of Chicago, and Seguin, of New York, was continued.

DR. R. W. AMIDON, of New York, then read a paper on

THE MYOGRAPH OF NERVE-DEGENERATION IN ANIMALS AND IN MAN.

As indicated in the title, the object of the paper was to present the results of study, by means of electric apparatus, of the effects of nerve-degeneration, the result of peripheral nerve-injury, in man as compared with animals. A myogram is a muscle-tracing; and after describing the apparatus—a simplified Marcy's instrument—by which the illustrations were obtained, Dr. Amidon directed attention to

three points: (1) The quickness of muscular contraction and relaxation; (2) the amplitude of muscular movement; and (3) the quickness of contraction after the appliction of stimuli, and the effect of continuance and withdrawal of the same.

The details of several experiments were given, and also the results of investigation of several cases of disease, "Bell's palsy of the face," etc., and some of the conclusions reached were as follows:

First.—There is an identity in the myograms as to form and relations in the human being and the frog in health.

Second.—There is great similarity in the pathological myograms.

Third.—There are marked myographic changes where slight trophic disturbances affect the muscles.

Dr. Amidon thought that when the cathode tracing was better than that given by the anode the prognosis was better that when the reverse existed.

The paper was discussed by Drs. Putnam, of Boston, and Morton, Rockwell, Seguin, and Birdsall, of New York, and closed by Dr. Amidon.

THE SYMPTOMS OF SANITY AND THE DIAGNOSIS OF INSANITY

was the title of the next paper, which was read by Dr. George M. Beard, of New York.

The object of the paper was two-fold: (1) to answer the question, How shall we know a sane man when we see him? and (2) to bring the law of evolution to bear upon the study of insanity. By investigating the normal condition of organs we obtain a knowledge of abnormal changes. A knowledge of the normal is essential to a proper study of the abnormal. The symptoms of insanity were studied under four heads:

First.—Activity of instinct of self-preservation.

Second.—Adaptation to environment.

Third.—Correspondence of character to age and station; and

Fourth.—Rememberable consciousness.

Dr. Beard had found the greatest difficulty in making a differential diagnosis between genius and insanity, as in either case the person was out of his environment.

The paper was discussed by the President.

Dr. James J. Putnam, of Boston, then read a paper, entitled

CONTRIBUTION TO THE STUDY OF CENTRAL MYELITIS,

The case reported was one placed under his observation by Dr. Shaw, of the Massachusetts General Hospital. The patient was a single woman, twenty-two years of age, who had been healthy up to the time of the present attack. A detailed clinical history was given. At the autopsy there were found numerous hemorrhages beneath the pleura pulmonalis. All the organs of the thorax and abdomen were normal. The Peyerian patches were thickened, and there was considerable ulceration of the mucous membrane of the rectum (the patient suffered from dysentery). The spinal cord was normal with reference to the membranes, but the substance was slightly softened in places. There was no meningitis (the patient suffered severely from pain referable to the back).

Microscopically the lesion was found occupying the central part of the anterior cornua throughout the entire length of the cord. There were signs of subacute inflammation in the immediate neighborhood.

The case had been interesting to him in three respects: (1) simply as a numerical addition to the cases of polio-myelitis in adults; (2) as showing the fact that a great deal of improvement may take place in symptoms while the lesion in the cord is permanent; and (3) as affording an opportunity to speak of the views recently advanced as to why this part of the cord is so often exclusively attacked.

Dr. Putnam then discussed at some length the views of Ross and others, and in continuation the subject was discussed by Drs. Miles, of Baltimore, Beard, of New York, Weber, of Boston, and Dr. Putnam.

The Association then adjourned, to meet at 8.30 P.M.

First Day, Evening Session.

Dr. Wm. A. Hammond, of New York, read a paper on

THE SO-CALLED FAMILY OR HEREDITARY FORM OF LOCOMOTOR ATAXIA.

The special point made by the author of the paper was, that neither clinically nor microscopically was there any evidence that the cases reported about twenty years ago by Friedreich, and one subsequently by Carre, as locomotor ataxia, also referred to by Erb, Leyden, Rosenthal, and Ross as cases of that disease, were illustrations of that affection.

Dr. Hammond then gave an outline of the clinical histories, and the results of autopsies so far as obtained, in Friedreich's cases, and also of the cases which had fallen under his own observation, making in all twenty-two in number. In all there were weakness of the lower extremities, gradually advancing upward, with freedom from pain; the pupils were equal, of normal size and reaction. The chief diagnostic symptoms of locomotor ataxia were absent. He regarded the cases as illustrating a distinct form of disease, probably originating in the cerebellum and medulla oblongata and extending to the spinal cord.

Dr. Seguin had met with quite a number of cases of the character referred to by the President, and he had diagnosticated disseminated sclerosis.

The President said that tremor on voluntary motion characteristic of disseminated sclerosis was absent. All his cases had originated in persons who were not of adult age.

Dr. Weber, of Boston, referred to cases in three families. With regard to tremor on voluntary motion as a symptom of disseminated sclerosis, he had seen one case, demonstrated to be such by autopsy, in which it was absent.

Dr. Seguin said that tremor on voluntary motion was frequently absent in disseminated sclerosis. He also thought that the symptoms of disseminated sclerosis should be extremely varied, because the distribution of the nodules was wholly irregular. He had also been struck by the fact that in some of these cases of so-called family ataxia there were pains, not so much in children as in adults. In the cases of children which he had seen there had been increased patellar tendon reflex.

Dr. Putnam remarked that in two of the cases referred to by Dr. Weber tendon reflex was absent in both when they were under his observation.

The paper was further discussed by Drs. Rockwell and Morton, of New York.

Dr. H. M. Bannister, of Chicago, then read a

NOTE ON BROMIDE MANIA, AND THE SUPPOSED COMPENSATORY ACTION OF EPILEPTIC ATTACKS.

The paper was a supplement to Dr. Bannister's contribution last year, on the effect which might be produced by the administration of bromides in epilepsy—namely, the development of acute mania. In only one-fifth of the cases of epilepsy which he had seen had the bromides affected the patient as indicated at that time.

Dr. Bannister discussed Stark's views concerning the effect produced by suppression of the epileptic attacks, and the paper was discussed by Drs. Spitzka, of New York, and Mills, of Philadelphia.

The next paper was read by Dr. E. C. Seguin, of New York, and entitled

A CONTRIBUTION TO THE CLINICAL STUDY OF ARSENICAL MYELITIS.

Three cases were reported in which the patients took Paris green, and the symptoms developed were such as to lead to the diagnosis of myelitis, resembling very much polio-myelitis, with some involvement of the sensory tract. The type was sub-acute in all three cases, and complete recovery took place under the use of galvanism and massage.

The President suggested that they were cases of poisoning from copper, and reported a case in which the patient had been poisoned with ammonia-sulphate of copper, and exactly similar symptoms developed. It would seem, therefore, to be more or less doubtful whether the condition was due to the arsenic or to the copper.

Dr. Wm. J. Morton, of New York, then read a paper on

MECHANICAL VIBRATION IN THE TREATMENT OF PAIN, AND A NEW PERCUTEUR.

It was discussed by Drs. Weber, Putnam, and Edes, of Boston; Miles, of Baltimore; Mills, of Philadelphia, and the President.

The Association then adjourned to meet at 2.30 P.M. Thursday.

Thursday, June 22d—Second Day.

The Secretary acknowled the receipt of communications from Dr. J. J. Mason and Dr. Schmidt, and also a note of regret from Dr. J. S. Jewell at his inability, on account of sickness, to be present.

The first communication to the Association was made by Dr. Putnam, of Boston, and consisted of the presentation of

A MICROTOME,

designed especially for making sections of the spinal cord, and also

A MODIFICATION OF POND'S SPHYGMOGRAPH,

so as to enable the operator to regulate the degree of pressnre upon the pulse.

Dr. S. G. Weber, of Boston, then read a paper on

LEAD PARALYSIS,

the object of which was merely (1) to give a brief review of the theories concerning the pathogenesis of the condition, and (2) to call attention to some unusual forms which simulate more serious disease.

After reviewing the theories, Dr. Weber concluded that lead paralysis does not depend upon a lesion in the spinal cord, but that it is primarily a neuritis, unless independent centres of lesion are to be recognized.

With reference to prognosis, it might be regarded as relatively favorable in recent cases. Dr. Weber then gave the histories of several cases, in one of which, especially, the symptoms pointed strongly toward myelitis, so that when first admitted to the hospital the diagnosis of myelitis was made. The urine was examined, in all his cases, by Prof. Wood, of Harvard, and lead was found. The lead line along the gums was absent in most of the cases. In only one was the source of the lead ascertained. The special point of interest was that lead-poisoning may almost exactly resemble myelitis.

Dr. Putnam, of Boston, referred to cases which resembled lateral sclerosis and also myelitis. Improvement took place under the use of iodide of potassium.

Dr. McBride, of New York, asked by what tests was the lead in the urine detected.

Dr. Weber did not know, but thought there could have been no doubt as to its presence, because repeated examinations were made by Prof. Wood in each case.

Dr. Seguin referred to a case of lead paralysis, in which the symptoms were apparently identical with those of polio-myelitis. It was one of those cases in which he thought it was impossible for the neurologist to make a differential diagnosis between the two diseases. There was trophic paralysis, without anæsthesia, and with pain. He believed that pain is present in many cases of polio-myelitis. He thought that lead paralysis is a form of polio-myelitis.

Dr. Weber thought that the pathology of the affection was still undecided, yet he believed the weight of evidence was in favor of its being, primarily, a neuritis. At all events the existence of lead paralysis without lesion in the spinal cord must be granted.

Dr. Miles, of Baltimore, thought that pain was absent in polio-myelitis in children, while Drs. Gibney, of New York, and Sinclair, of Philadelphia, were quite sure that children with this disease suffered from pain.

The President said that formerly he entertained the opinion that the paralysis was due to a central lesion, but he had come to believe that in the beginning the lesion was peripheral, and produced by actual contact with lead.

With reference to Dr. McBride's question, it was well-known that lead is not excreted by the kidneys under ordinary circumstances, but it appears in free quantities after the use of iodide of potassium. The best test of which he knew was the galvanic. Take a piece of bright copper, drop a drop of urine upon it, and with a little piece of sheet silver touch both the copper and the drop of urine at the same time, and if lead is present it will leave its stain upon the copper.

Dr. Edes, of Boston, doubted the introduction of lead into the system through the skin.

Dr. Charles K. Mills, of Philadelphia, then read a paper on

BRAIN TUMOR.

It contained the notes of twelve cases and they were studied chiefly with reference to diagnosis.

Headache was present in every case. The pain was continuous, sometimes of persistent severity, and always there were exacerbations of great violence.

Percussion of the skull was practised in three cases, and it intensified the pain in the region corresponding to the situation of the tumor. He believed that percussion of the skull might afford valuable aid in localizing tumors.

Vomiting was present in eight out of the twelve cases. It was absent in the cases in which the tumor was situated in the frontal region.

Vertigo, including dizziness, giddiness, reeling, insecurity in the erect posture, etc., was present in ten cases.

Mental disturbance was present in all the cases, but chiefly of an emotional character.

Anæsthesia, more or less impaired sensibility, was present in seven cases.

Choked disk existed in five cases; descending neuritis in three cases.

The temperature of the head was taken in five out of the twelve cases, and in all it was elevated. The conclusions reached were: 1, that a general diagnosis of intra-cranial tumor could be made with greater certainty than any other intracephalic disease, and the diagnosis may be based upon headache, percussion of the head, vertigo, vomiting, choked disk; 2, that a local diagnosis could be made with great positiveness from a study of the symptoms present in some cases and in others by exclusion; 3, that tumors of the cortical motor zone could be diagnosticated early; 4, that tumors of the frontal lobes could be diagnosticated by exclusion; 5, that tumors of the parietal and occipital lobes could be diagnosticated by sensory symptoms; 6, that large tumors of the pons could be localized; 7, that small growths might be localized in one of the four quarters of the pons in most cases; 8, that tumors of the cerebellum could be diagnosticated with considerable certainty.

Dr. Putnam, of Boston, thought choked disk in the early stage was only a form of neuritis, and that the distinction made between the two conditions by Dr. Mills was not real or practical.

Dr. A. D. Rockwell, of New York, referred to a case in which there were apparently positive symptoms of brain tumor, and autopsy revealed the fact that no tumor existed.

Dr. Miles, of Baltimore, thought there was difficulty in diagnosticating as to whether the symptoms were due to destructive lesion or to pressure.

Dr. Seguin recognized the importance of headache as a symptom, but in two cases under his observation there was no headache whatever.

With reference to neuritis and choked disk, it was present in only *one* of his eight or nine cases of strictly cerebral tumors; but existed in all his cases of basal or cerebellar tumors. He thought it was not well to reject brain tumor when symptoms of tumor were present, although choked disk was absent.

Several of his patients with brain tumor had exhibited an undue susceptibility to chloral, and he was obliged to use morphine to secure rest and relief from pain. The paper was further discussed by Drs. Amidon and Birdsall.

Dr. Mills, in closing the discussion, thought his cases decisive as to the difference between choked disk and true descending neuritis. Of course it was a mooted point, but his own opinion was that in cases of brain tumor there was, according to the position and character of the growth, either choked disk from mechanical causes, or descending neuritis or peri-neuritis by continuous process from the seat of the lesion. He was inclined to favor the lymph-space theory in explanation of choked disk. Dr. Putnam's idea that choked disk and neuritis are practically the same was true so far as successive steps were concerned, but Dr. Mills believed that the initial step was mechanical and not inflammatory. He was unable to explain why choked disk was absent in so many of Dr. Seguin's cases, and so uniformly present in his own.

With reference to general symptoms, intracranial tumors were, in most of the cases he had seen, tumors of the membranes of the brain. Headache is a symptom of irritation of the membranes, and its occasional absence might be due to the fact that the tumor was not situated in the membranes.

Dr. A. D. Rockwell, of New York, then reported

A CASE OF POST-PARALYTIC CHOREA, WITH REMARKS ON THE TREATMENT OF CHOREIC SYMPTOMS IN GENERAL.

The case was treated by the use of ether spray to the spine, the internal administration of the fluid extract of conium, and the application of central galvanism. He regarded the ether spray as of but little value; had much more confidence in conium, but could not speak of it in very positive terms; regarded faradization and central galvanism as most beneficial agents.

Dr. Morton, of New York, thought that ordinary cases of chorea would get well under any severe treatment; but he did not think they would get well of themselves. He had used a jet of cold water directed against the spine, and with good results, a plan much adopted upon the continent.

Dr. Edes thought that conium must be given in doses of sufficient size to produce its physiological effects in order to be beneficial. He was satisfied with the arsenic treatment.

Dr. Seguin and The President were satisfied with the arsenic treatment.

Dr. Græme M. Hammond reported

A CASE OF ATHETOSIS RELIEVED BY NERVE-STRETCHING.

Athetosis is universally regarded as an incurable disease. The first attempt to relieve these patients by nerve-stretching was made by Dr. W. J. Morton. Dr. Hammond's case was the second, and the patient was the original, published by Dr. W. A. Hammond in his treatise on "Diseases of the Nervous System." On May 27, 1882, assisted by Dr. Osborn, he stretched the median nerve, applying only a very mild degree of force. The result had been that the patient (patient exhibited) could open and shut his hand at will, take off his coat, write his name and address, things which he had been unable to do during the last twenty-three years. The hand and arm were also quiet during the night, as also was the leg, and only two epileptic seizures had occurred since the operation. Dr. Hammond believed that the lesion of the affection was situated in the corpus striatum, and that the benefit which followed nerve-stretching was due to the fact that the nerve was thereby rendered incapable of transmitting impressions fully.

The paper was discussed by Dr. W. J. Morton and the President.

The Association then adjourned, to meet Friday, at 2.30 P.M.

Friday, June 23d—Third Day, Afternoon Session.

The Council recommended the election of Dr. Charles L. Dana, of New York, as an active member, and Auguste Ollivier, of Paris, and Merzejewski, as associate members. Adopted.

The first paper was read by Dr. V. P. Gibney, of New York, and contained the report of

A CASE OF POLIO-MYELITIS, ALSO TWO CASES OF COMPRESSION OF THE SPINAL CORD BY THE ODONTOID PROCESS.

After giving the clinical history of the case of polio-myelitis (infantile spinal paralysis), Dr. Gibney described the lesions found in the cord as illustrated by microscopic preparations prepared with the assistance of Dr. R. W. Amidon. Sections were made from the brachial enlargement and the lumbar region. In the brachial region they showed macroscopically considerable shrinkage of the left anterior cornu, and microscopically there were found remaining only one or two ganglion cells; but upon the opposite side there were cells in abundance. In the sections from the lumbar region there was a notable diminution of ganglion cells in both anterior cornua, while in the cervical region there was quite marked changes in the columns of Türck.

The first case of compression of the spinal cord by the odontoid process had already been reported by Dr. Yale at the New York Surgical Society. [See Medical Record, vol. xviii., p. 555, in illustration of disease of the upper cervical vertebræ.]

The second case was one in which the compression was of four months duration. The principal changes found in the cord at the point of compression involved those parts of the white matter in the lateral columns which are next to the posterior cornua, extending out into the parts which represent the true cervical pyramidal fibres. The sections above the point of pressure showed less change. They were unable to trace any true degeneration.

Dr. W. J. Morton, of New York, referred to a specimen, which Professor Darling found in the dissecting-room at the University Medical College, and in which there had been fracture of the odontoid process. The patient must have survived the injury for some time, because the fragments had become firmly united.

Dr. William A. Hammond then read a paper on

THE DISEASE OF THE SCYTHIANS, MORBUS FEMINARUM, AND ANALOGOUS CONDITIONS.

The first mention made of it was by Herodotus, and the next by Hippocrates, who said that among the Scythians many impotent persons were encountered with high-pitched tone of voice, appearances and habits of women, etc., the tradition being that the condition was produced by God, but which the Father of Medicine believed was no more of divine origin than any other disease.

He attributed it indirectly to horseback riding and directly to division of veins near the ears which were supposed to be in close relation with the genital organs, the result being atrophy.

Dr. Hammond reviewed the history of the subject and was led to the conclusion that there was good reason for believing that among the male Scythians and the Tartars there were many who were the subjects of sexual impotence, which caused them to look like women and acquire the instincts of the female sex.

Thirty years ago, when stationed in Mexico as a member of the medical corps of the United States Army, his attention was directed to this subject, and by the personal favor of the chief of one of the tribes whom he had treated for rheumatism, he was permitted to see and examine one of these persons who, it was said, had been changed from a man into a woman. There was an extraordinary development of the mammary glands and the person had nursed several children whose mothers had died. There was no hair upon the pubes; the penis was shrunken so that the glans was no larger than a thimble and of about the same shape, the length about an inch and a half, the scrotum long and pendulous and it contained the remnants of two testicles not larger than filberts. The man was thirty-five years of age, and the evidence seemed unquestionable that when a man, his genitals were much above the average size. There was no deformity of any kind. The man was dressed in woman's clothing, was following the occupation of women at the time, that of grinding grain.

A second person was seen subsequently, thirty-six or thirty-seven years of age, and he found the same physical condition, except that there was no remarkable development of the mammary glands.

After a time he succeeded in learning that such persons were regarded as essential in the orgies and pæderastia of the tribes and that they were produced in the following manner: One was selected who had the greatest virility and attouchement practised upon him several times daily, also subjected to horseback riding severely, and finally orgasm becomes impossible, the genitals shrink and the man gradually changes into a woman.

The essential point in these cases was the mental alienation that had its origin in sexual impotence, produced by excessive masturbation and horseback riding.

The case of Lord Cornbury, one of the early Governors of New York and New Jersey, was cited, and other instances during the discussion, where men had an apparently uncontrollable desire to appear in the dress of woman.

HEMORRHAGE INTO THE PONS—PATIENT SURVIVED ELEVEN MONTHS AFTER THE ATTACK.

Dr. F. T. Miles, of Baltimore, reported a case. The patient was a woman, forty years of age, who was suddenly paralyzed, in June, 1881. There was unconsciousness. hemiplegia, pannus of the left eye, total deafness in the left ear.

The remarkable points in the case were that the abducens escaped, that there was paralysis of sensation confined entirely to one branch of the fifth pair, with destruction of the eye beginning almost immediately, and the position of the hemorrhage was quite out of range of the pyramidal tracts to account for the right hemiplegia which existed to the last.

Dr. Spitzka thought the pyramidal tracts were involved.

Dr. C. L. Dana, of New York, read a paper on

STRETCHING THE SPINAL CORD.

It will be published in full in a subsequent number.

Dr. W. J. Morton referred to a case in which subcutaneous stretching of the sciatic nerve was followed by benefit.

Dr. Edes asked as to the minimum force required to pull the sciatic nerve out.

Dr. Græme M. Hammond asked whether Dr. Dana in his experiments applied the extending force so as to make traction in the direction of the spinal cord, or was it exerted in the middle of the nerve so as to be as much one way as another.

The President thought that the spinal was stretched when the sciatic nerve was stretched by the cutting operation, and he was positive that he

had stretched it by subcutaneous stretching of the sciatic nerve. So far as experience extended, subcutaneous stretching of the sciatic nerve was not painful, and it was also impossible to stretch it subcutaneously in corpulent persons, because of the inability to bring the thigh in sufficiently close contact with the chest.

Dr. Dana said he was very sceptical concerning stretching the spinal cord by stretching the sciatic nerve subcutaneously in the living subject. So far as he had been able to ascertain, the minimum amount of force required to pull the sciatic nerve out by the roots was 130 pounds. With regard to measuring the amount of force really used, as suggested by Dr. Græme Hammond, it was a very important question, for by raising upon the nerve with ten pounds was really pulling upon the nerve in the direction of the cord not more than five pounds.

Dr. Morton thought there should be no doubt as to the efficacy of subcutaneous nerve-stretching in sciatica. Probably the nerve was more easily stretched in disease than in health. He suggested that the sciatic nerve of a fat man could be stretched subcutaneously by carrying the leg somewhat outward alongside of the body partially toward the shoulder.

Dr. Dana thought it a mistake to suppose that by subcutaneous stretching of the sciatic nerve we affect the spinal cord. In all cases of subcutaneous stretching the patients get up and walk away; whereas when the nerve is exposed and pulled upon there is some impairment of locomotion. Perhaps the nerve was stretched, but he doubted if the spinal cord was very frequently by this method.

POSTERO-LATERAL DEGENERATION.

Dr. R. T. Edes, of Boston, reported a number of cases in which severe concussion seemed to be the cause of the above lesion. Microscopic slides accompanied the communication.

Dr. Edes also exhibited a *percussor*, devised by one of the members of his hospital staff, which he had found very useful in testing the tendon reflex in the upper extremities and parts of the body. He thought that with some practice tendon reflexes could be counterfeited very well.

The Association then adjourned to meet at 8.30 P.M.

THIRD DAY, EVENING SESSION.

Dr. William J. Morton, of New York, read a paper entitled

NOTES ON THE PROGRESS IN STATIC ELECTRO-THERAPEUTICS DURING THE LAST YEAR.

A *résumé* was given of the improvements in instruments and their accessories that had been made, and a somewhat extended reference made to the diseases in which he had obtained results sufficiently good to be worthy of note.

In general he had found it serviceable in paralyses where other forms of electricity had either failed or ceased to act, in neuralgias, spinal irritation, rheumatism, and hysteria in all its forms.

He had employed it with marked benefit in anæsthesia, hemiplegic or hysteric, in neuritis, progressive muscular atrophy, angina pectoris, hysterical aphonia, spasmodic asthma, Bell's paralysis, diphtheritic paralysis, etc. In chorea the results had been unsatisfactory, and in locomotor ataxia, relief for some of the symptoms had been given, but no permanent results had been obtained.

Dr. R. W. Amidon, of New York, thought that static electricity possessed no special advantage over the dynamic, except as a counter-irritant and a slight tonic or stimulant, perhaps, in some cases, and as an excitor of the imagination. It was doubtless a useful method of treatment where the influence of the imagination was of advantage as in hysteria, but the same results could be obtained by the use of magnets, mustard plasters, etc.

Dr. Græme M. Hammond referred to four cases of progressive muscular atrophy which had improved to a remarkable extent under the use of static electricity. Under faradism, only slight muscular contractions could be obtained, but static electricity produced full contractions.

The Secretary presented

MICRO-PHOTOGRAPHS OF CERTAIN PORTIONS OF THE BRAIN OF THE IGUANA TUBERCULATA,

accompanied by a letter from Dr. J. J. Mason, of Newport, R. I.

Dr. Birdsall, of New York, then read a note on

THE SLEEPING DISEASE OF AFRICA.

The communication contained a description of this affection as seen among the negroes on the west coast of Africa, sent to him by Dr. G. H. Bachelder, together with a synopsis of the literature of the subject so far as he had been able to review it. The essential feature of the disease is an irresistible tendency to sleep, which continues for a varying length of time, average two months, and terminates fatally. The appetite remains undisturbed. According to Guerin, who had seen 125 cases and made 32 autopsies, it is a disease which has various causes, but peculiar to the African race, and produces passive congestion of the brain and its membranes. Clark directs special attention to the enlargement of the deep seated cervical glands, and another writer says that the native physicians remove the glands so affected, and that in that manner a cure is always affected. Dr. Bachelder speaks of an initial lesion in the nasal mucous membrane.

Dr. Seguin referred to a case occurring in a negro in New York, in which there was an unmistakable tendency to sleep, and there was no apparent disease about the man. He did not know the result.

The paper was further discussed by Drs. Morton and Birdsall.

Dr. E. C. Seguin, of New York, then reported

A CASE OF VERTEBRAL CANCER WITH PARAPLEGIA.

The patient had had cancer of the breast, which was removed, recurred, and a second operation was performed. Subsequently she suffered from an exceedingly painful paraplegia, and a tumor developed in the lower lumbar region. The bones viewed externally after death seemed nearly normal. On section, a projection was found within the canal in the eighth or ninth dorsal vertebræ, which compressed the cord. There were masses of cancer in the bodies of the vertebræ; one in the eleventh dorsal, smaller ones in others, a large mass in one of the lumbar vertebræ. There was no cancer of the dura mater. The cord itself was the seat of a high grade of myelitis. There was no evidence of descending degeneration. The cancer was of the ordinary variety with a large amount of fibrous tissue.

A paper by Dr. Schmidt, of New Orleans, accom-

panied by illustrations and microscopic sections, was read by title:

TUMOR IN THE FOURTH VENTRICLE UNACCOMPANIED BY SPECIAL NERVOUS SYMPTOMS.

THE PRESIDENT thanked the members for their uniform courtesy, wished them all a safe return to their homes, and declared the Association adjourned, to meet on the third Tuesday in June, 1883.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS.

Stated Meeting, May 25, 1882.

DR. H. C. CRAMPTON, PRESIDENT, IN THE CHAIR.

DESCRIPTION OF OPERATIONS FOR RESTORING THE FEMALE PERINEUM AFTER LACERATION THROUGH THE SPHINCTER ANI, AND THE SUBSEQUENT MANAGEMENT WITHOUT CONSTIPATING THE BOWELS.

DR. H. T. HANKS, M.D., read a paper on the above subject (*vide* page 1).

DR. A. C. POST being called upon to open the discussion, would only say a word regarding the needle called Peaslee's. It had been introduced by Dr. Alexander H. Stevens, and he had had one in his possession long before Dr. Peaslee. He did not know whether it was original with Dr. Stevens.

DR. I. E. TAYLOR said he had ceased to operate much during the last few years, but he was surprised to hear of so frequent failures in the operation on the part of those mentioned by Dr. Hanks. He did not know of a more simple and efficient method of performing this operation than that resorted to by James L. Lane, of London, and which he, Dr. Taylor, probably as the first one in this country, had adopted. The finger was passed up the rectum, such cutting done as was necessary, a needle (Buck's was the one he employed) was passed through the tissues above, and a very fine silver wire suture drawn through; then below three or more times, as might be necessary; the wires were twisted, and the parts let alone ten days or less, according to circumstances, and afterward the lacerated perineum was treated, or this might be done at once if the laceration had not extended into the rectum. The parts were denuded a little higher up than Dr. Hanks had mentioned, and brought together by clamps. He preferred lead ones. He seldom resorted to opium to produce constipation. Sometimes he injected a little water. He believed this method of operating was generally attended with success.

DR. CHARLES C. LEE had heard but the latter part of the paper. He had had both the fortune and the misfortune to operate in a number of cases of laceration through the sphincter into the rectum; misfortune, because in a number of cases the operation was a failure, and he believed this was justly attributable, as Dr. Hanks had said, to locking up the bowels a sufficient length of time for the formation of large scybala which destroyed the results of the operation at the time of the first movement. In all but one case, in which erysipelas broke out before this time, he believed his failures were due to the above cause. It was very necessary to twist the sutures passed through the rectal tissue very lightly, for these tissues were friable and liable to be torn through, if the sutures were twisted tight. He was in the habit of examining the parts carefully on the eighth day, and, if proper, take out the sutures, otherwise leaving them until the tenth day. While he had had a fair proportion of successes in cases in which the bowels were confined, he was satisfied the percentage would have been much greater had he kept the bowels loose, as in a number of other cases he had done. Indeed, there had not been a single failure in cases where the bowels were kept loose; and he had pursued this course in several instances. The vagina was carefully irrigated, and he saw the patient every day himself, exercising great care to have his instructions carried out fully.

DR. MUNDÉ said the operation for laceration of the perineum through the sphincter ani was a very rude one as late at least as 1860. The first person who performed the operation with a full appreciation of the anatomy of the parts implicated, was Simon. When in Heidelberg, years ago, he assisted Simon at a number of his operations for this pathological state, and he now remembered very distinctly the steps of the operation, the great care exercised, and how tedious it was, requiring from one to two hours. It was done essentially as Dr. Hanks had described. The rectal sutures were of the finest variety of Chinese silk. The bowels were not constipated, but kept loose by the compound licorice powder, or other means, having a soft movement every day, and his results were exceedingly good. He did not believe that a failure occurred while he was assisting him. Dr. Mundé, however, had never done Simon's operation, but always employed Emmet's, which was easier and more simple, and by keeping the bowels loose he had excellent results, both in the large number of cases in which the sphincter was not torn through, and in the fewer in which this and the rectum were involved. For two or three days before the operation he gave the compound licorice powder, or equal parts of powdered sulphur. of sulphate of magnesia, and of bitartrate of potash in a glass of water before breakfast, so as to render the fæces soft. On the morning of the operation he gave an enema of warm water or water and soap-suds, and another half an hour before the operation, so as to avoid the liability of a discharge at an inopportune moment. A vaginal injection was also made at the same time. The bowels were left alone two or three days after the operation, having been thoroughly cleaned out before, and, the diet being fluid, making little fæces. As soon at least as the morning of the third day he gave the compound licorice powder or the sulphur mixture, according as the one or the other was more suitable in the particular case, and when the patient was about to have a movement, an injection of sweet-oil was made, and afterward of warm water, or water and soap-suds. An evacuation was had every day subsequently, except on the day when the sutures were removed, so as to avoid possibility of damage to the fresh wound. In no operation were the services of a skilled, careful nurse more needed. She must avoid, in making vaginal injections, forcing the stream directly against the wound, or allowing scybalous masses to pass through the rectum, etc.

DR. HUNTER had operated for laceration of the perineum a number of times, making use of Emmet's method, and in the cases in which the tear extended through the sphincter the patient afterward had complete control of the fæces and gases. He attributed his success largely to passing the sutures quite deeply, and to do this he used a long straight needle, passing it half-way, withdrawing it, then reinserting and passing it through the opposite wall,

when the wire was pulled through. In vivifying the surfaces, he employed scissors of a shorter handle and greater curve than Emmet's, and having a wide surface on either side the pivot, causing close coaptation of the blades at all points.

Dr. Chamberlain had little experience with the degree of rupture of the perineum mentioned, but for lesser degrees treatment in his hands had been more satisfactory than for any other plastic operation. The point referred to by Dr. Mundé was very important, namely, to have the patient avoid any straining during the movement of the bowel, placing her on the side in a position to prevent this. A class of cases somewhat related to those mentioned this evening was where a chancroidal ulceration made a communication between the rectum and the vagina. One of the worst and most disagreeable cases of this kind he had ever seen he treated at the suggestion of Dr. Keyes, by having the patient sit in water of 90° or 100° F. eighteen hours out of the twenty-four, and for a long period. The benefit derived from it was very great, so that the patient considered herself well enough to leave the hospital without a plastic operation which he now proposed to do. The scissors he employed in repairing lacerations of the perineum were sharp only at the point, back of that being rounded. The needle was straight, and was passed as Dr. Hunter had described, but he had been unable to insert the sutures so deeply as Dr. Hunter had mentioned.

In about forty cases of laceration of the perineum in various degrees, Dr. W. G. Wylie had had scarcely a single failure, and in all the bowels were kept constantly open. He considered it of the greatest importance to pass the needle below the white fibrous tissue of the perineum, otherwise it would have no more effect than if the surfaces of the skin only were drawn together.

The President remarked that more emphasis might be placed upon the benefits to be derived from the use of hot water. In order to check hemorrhage it should be of a temperature of 120° F.

The society adjourned.

The Value of Woorara in Medicine is described, and somewhat exaggerated, by Dr. B. A. Watson (*Virginia Med. Monthly*). Its only pronounced usefulness so far has been in rabies. Dr. Watson says that a rather cursory examination of the medical literature for the last six years reveals the fact that woorara has been employed in the following diseases with the accompanying results:

	Whole Number of Cases.	Recovered.	Improved.	Not Improved.
Rabies	17	4	7	6
Tetanus	23	11	..	12
Epilepsy	80	5	..	75
Catalepsy	1	..	..	1
Chorea	2	..	2	..
Paralysis agitans	1	..	1	..

As regards the dose he suggests that, in cases of rabies or traumatic tetanus, where promptness in action may save the life of the patient, the first injection should be only one-sixteenth of a grain, *but that this dose should be doubled every half hour until its full physiological action is secured* or the patient completely relieved.

Correspondence.

MALARIAL MANIA.

To the Editor of The Medical Record.

Dear Sir: I see much is being written on this subject, and think with H. (Medical Record, October 9, 1880, p. 416), and G. M. D. (*idem*, October 30, p. 500), that something more is required than "marsh poison" to produce intermittent fever. G. M. D. hits the nail on the head when he speaks of "hot and cold nights." I would suggest the more careful study of changes in temperature in so-called malarious districts; and in this connection would invite the attention of advocates of the malarial theory to a careful perusal of Oldham's "What is Malaria?" published by H. K. Lewis, Gower Street, W. C., London and Wyman & Co., Calcutta, 1871.

I could cite case after case in corroboration of the views of Oldham; two, however, I think will suffice.

For six months I lived in the centre of a cane field in a village of about three thousand people, in a notoriously unhealthy district. The immense fields of cane were constantly supplied by running water. The heat was intense during the day, being somewhat tempered, however, by a strong southwest wind, which in the night reversed its direction and blew down from the snow-clad peaks of the Andes. The change of temperature from midday to midnight was, on an average, 40° F. I observed that those persons who remained within doors after *sunset* were never troubled with intermittent fever. A New Orleans lady, who was residing on the estate, said to me on my arrival, "Doctor, do not go out of your room after sunset and you will not get the chills, or if you are obliged to do so put on a *thick* coat." I followed her advice to the letter and never had a chill.

During the construction of the Oroya Railway, one of the most sickly sections was at an altitude of 5,280 feet, where the most ardent advocate of malaria would say that marsh poison was an absolute impossibility. There was also a rapid mountain stream fringed by willows running at the rate of about eight miles per hour in the bottom of the valley, along which were constructed the camps of the laborers. One thousand feet up on the mountain side, in hard rock or pure granitic sand, was the line of the railway. The heat during the day was intense, often as high as 110° F. in the shade, falling in the night to 60° F.! What was the result? Men working from 6 A.M. to 6 P.M., in a burning sun, almost nude, descending 1,000 feet to the bank of the river, eating their dinners, lounging about, drinking and gambling, and with that great change of temperature, intermittent fever was developed in its worst and most fatal forms; congestions of every organ, and death of frequent occurrence in six hours. I would here remark that before going to work coffee or tea, bread, and sugar were served out, the breakfast hour being 10 A.M., for which an hour and a half was usually allowed. Pure fresh water was furnished during the day *ad lib.* My own experience was this: my house was situated upon a barren rock about 2,000 feet above the river, but I was obliged to descend into the valley every night, and after being scorched all day it was deliciously cool riding down the mountain side in

the *same* clothes I wore during the day. Result, in eighteen days a violent chill.

Some will say that my system was poisoned by my previous residence in a highly malarial district. To this I answer: first, that I had passed two months at sea; second, that I had taken nearly half an ounce of quinine, besides brandy and bark. I was a firm believer in prophylactics in those days, at least as regards quinia against intermittents. My friends all advised me against such a course, saying that I would have the fever the "worse for it." I continued, and found that experience was better than theory. Quinine would not prevent, but would rather aggravate the attack. (This I have proved, at least to my satisfaction, many times.) Once the chill was on, a mercurial purge and *then* the quinine, preferably subcutaneously. My experience—and it has not been small—coincides exactly with Oldham, that malaria is chill, or at least exposure to cold.

One of your correspondents says that the insane in one of the asylums of New Jersey do not have the disease. They do not go out after sunset.

I do not believe in the bacterial theory, but do believe that there is some sort of systemic poison. At this altitude (15,000 feet) persons coming from the coast very often have severe attacks of intermittent fever, difficult of cure, and frequently terminating in typhus and typhoid, which are here *endemic*. This frequently occurs, although they may not have had, or at least deny having had, intermittent fever on the coast.

These observations should have reached you long ago but for the almost entire interruption of postal communication with the interior, owing to the war.

Yours truly, etc.,

GEO. A. WARD, M.D.

CERRO DE PASCO, PERU, April, 1882.

NERVE-STRETCHING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your readers may feel some interest in the following case, as nerve-stretching is now "on trial:"

Lieut. R. C——, U. S. Navy, aged thirty-five, native of Maryland. Neuralgia of the left ulnar nerve, resulting from an injury received on board the U. S. S. Wyoming, in May, 1881, while at sea. In a heavy swell he was thrown, by a sudden lurch of the ship, over the back of a chair, and fell on the deck, striking the left elbow with great force. Severe pain followed, which lasted but a few minutes, and then passed away.

On the following morning, sensation had diminished in the little finger and adjoining side of the ring finger, and there was a return of pain in the forearm. This condition continued for some weeks, when the pain became much aggravated by protracted use of the arm, in writing for some hours, upon a marble table. There were also, at this time, manifestations of malarial poisoning, to which he had previously been subject. A stay of some weeks in the country afforded no relief; on the contrary, the pain increased in intensity, extending from the shoulder the whole length of the arm, along the course of the ulnar nerve. He was then admitted into the Naval Hospital at New York, where he was treated with quinine, counter-irritation over the seat of pain, hypodermic injections of morphiæ sulph. with only temporary relief. Shortly afterward, being transferred to Washington, he came under the care of Surgeon A. A. Hoehling, U. S. N., who continued the same line of treatment, with the addition of potassium iodide, gr. v. twice daily.

The pain had now become excruciating, necessitating the constant use of morphia hypodermically, with consequent disturbance of the bodily functions. It was, therefore, determined to resort to nerve-stretching, and Surgeon-General Wales was invited to perform the operation, which was done by him August 2d. The ulnar nerve was exposed at the point of passage over the internal condyle, and was forcibly stretched, the weight of the arm being allowed to suspend from the nerve held upon the handle of the knife. The wound was closed with wire sutures and dressed antiseptically. Immediate relief from the pain followed.

In a few days it returned, and was as severe as before, so that he had to use morphine again. He then went to the Sulphur Springs, and was there seized with typho-malarial fever. Two days after the fever set in the pain left his arm, and has not returned. There is a little numbness in the fingers originally affected. He took forty grains of quinine daily for a month, he says, though it seems almost incredible; this was while he had the malarial fever. He was seen by me on March 13, 1882, and was perfectly well, excepting the slight numbness above mentioned.

Very respectfully,

P. S. WALES,
Surgeon-General U. S. Navy.

Obituary.

WILLIAM HARRISON STUDLEY, M.D.,

NEW YORK.

THE whole community of Yorkville was startled and grieved by the announcement of the death of this physician, which occurred on the morning of the 14th ult., at his residence, 160 East Fifty-third Street. A sudden attack of malignant pleuro-pneumonia, resisting all efforts of his professional brethren to control, reached a fatal termination in the brief space of three days. In his death the medical profession has lost one of its most learned, most industrious, and most successful members.

Doctor Studley was born in Bridgeport, Conn., February 21, 1827. He graduated in the class of 1850, at Trinity College, Hartford, taking the highest honor of the *Phi Beta Kappa*. In 1852 he graduated from the Berkley (Protestant Episcopal) Divinity School of the same city and was ordained to the ministry by Bishop Brownell. Zealously serving in this field for two years, in different parishes, a failure of health compelled a change of occupation. He therefore began the study of medicine in Chicago, Ills., at the Rush Medical College, and as a member of the class of 1860, received his degree from the College of Physicians and Surgeons of this city. He immediately opened an office in the then suburban village of Yorkville, in which neighborhood, with the exception of two years of professional life in the army, during the rebellion, he labored to the last. Within the last few years Dr. Studley had given much attention to gynecology, to which department he contributed many inventions and improvements of surgical instruments, as well as to its literature many essays and monographs. An extensive and lucrative practice enabled him to leave his family, a widow and four children, in comfortable circumstances.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 18, 1882, to June 24, 1882.

MAGRUDER, D. L., Major and Surgeon, Medical Director of the Department. The leave of absence granted him from Headquarters, Dept. of the Missouri, extended fifteen days. S. O. 64, Military Division of the Missouri, June 22, 1882.

HOFF, J. V. R., Capt. and Asst. Surgeon. Having reported at these Headquarters, is assigned to duty as Post-Surgeon at Alcatraz Island, California. S. O. 107, Military Division of the Pacific and Dept. of California, June 17, 1882.

NOTSON, WM. M., Major and Surgeon. Died at Columbus Barracks, Ohio, June 23, 1882.

MOFFATT, PETER, Capt. and Asst. Surgeon. Died at Fort Cœur d'Alene, Idaho, on June 15, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending June 24, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
June 17, 1882.	12	8	79	8	65	46	5	0
June 24, 1882.	14	8	108	9	50	73	8	0

THE LATE DR. WILLIAM H. STUDLEY.—The following resolutions were adopted by the Yorkville Medical Association, June 23, 1882:

Whereas, Our late associate, WILLIAM HARRISON STUDLEY, M. D., so recently removed to the abode of the immortals, eminently deserves a tribute to his earthly memory; therefore be it

Resolved, That as one of its founders, the Yorkville Medical Association, whose interests he promoted by many valuable written contributions, and in whose debates he was always conspicuous, deplore the loss it has sustained by his sudden taking off.

Resolved, That his record has been that of a gentleman, whose graces won him hosts of friends, whose many-sided culture commanded universal respect, and whose integrity was ever beyond suspicion.

Resolved, That we tender to his family and kindred our sympathy, with the assurance that not only this association but the community at large has lost its brightest ornament.

Resolved, That copies of these resolutions be furnished to the medical journals of the city and to the family of the deceased.

FRANCIS A. THOMAS,
JAMES R. MACGREGOR,
JOHN SHRADY,
H. A. C. ANDERSON,
WHITMAN V. WHITE,
Committee.

DR. J. G. THOMAS, of Savannah, Ga., has been in our city for a few days, having returned from the meeting of the American Medical Association at St. Paul. Those of our readers who are familiar with the history of State medicine in the United States will remember that Dr. Thomas was a few years ago sent to the Legislature of Georgia to represent the sanitary interests of Savannah, and that it was largely through his intelligence and fidelity to duty that the law was enacted which gave to that State a good health board, which at its first organization made him its president. He has been active in the affairs of the National Health Association, and called upon by the National Board of Health for co-operation in many critical junctures. Those who visited Savannah last November, to attend the session of the National Health Association, had occasion to remember with grateful appreciation his generous hospitality, to see also how faithful he was to every professional trust, and what honor he reflected upon his vocation.

AN INJUSTICE TO "THE CENTURY."—We regret that through a mistake an item, headed "A Disappointment," was made to say that *The Century* had advertised the notorious "Dr." Flower. As a matter of fact, we are told that *The Century* does not advertise patent medicines at all. Our item is true, however, of *Our Continent*, and it was that journal not *The Century* which was in mind at the time.

THE ENTERPRISE OF AMERICAN DRUGGISTS.—Some few weeks ago I referred to the fact that the American drug houses, through their agencies in this country, appear to be slowly, yet none the less surely, supplanting our English drug houses. This is being done by persistent and extensive, one might almost say reckless, advertising. In the matter of pushing business, Brother Jonathan is far and away ahead of John Bull; and if John of the drug stores does not mind what he is about, he will wake up one fine morning and find that, while he has been sleeping, Jonathan has improved the occasion by securing all his best customers.—*Students' Journal.*

TO RENDER DRESSES, MUSLIN, ETC., NON-INFLAMMABLE.—

℞. Pure sulphate of ammonia...	8 parts.
Pure carbonate of ammonia..	2½ "
Boracic acid.....	3 "
Starch, dextrine, or gelatine.	2 "
Water.....	100 "

AN EXCELLENT PLAN.—The Cincinnati Academy of Medicine will give annually a gold medal to the member who contributes the most valuable paper.

THE BALTIMORE ACADEMY OF MEDICINE renews its prize of $150 for the best paper offered upon a medical subject; the subject to be chosen by the writer.

IODOFORM IN ULCER OF THE STOMACH.—Mr. J. M. Redmond, of the Mater Misericordiæ Hospital, Dublin, reports a number of cases in which iodoform seemed to be of great benefit in ulcer of the stomach. It was given in pill-form, in three-grain doses, three times a day.

M. AMÉDÉE LATOUR has resigned his position as editor of *L'Union Médicale*, a leading medical semi-weekly. Dr. Richelot is now editor. Dr. Latour has conducted the journal for thirty-five years.

THE GERMAN CONGRESS OF NATURALISTS AND PHYSICIANS will meet this year on September 17th.

HOW TO SETTLE THE CHLOROFORM QUESTION.—Give ether.

SINCE THE BEGINNING of the chloroform discussion before the French Academy of Medicine, three deaths have been reported from the use of that anæsthetic.

THE DOCTOR ON THE BICYCLE is becoming a frequent sight in England. THE RECORD made a plea for their use in this country some time ago. There are a good many regions where they could be used to advantage.

STRETCHING THE OPTIC NERVES.—M. Parnard, of Paris, stretched both optic nerves for atrophy accompanied with vertigo and intense pain. The right nerve was pulled so hard that it broke. The patient experienced some benefit, but died a month later "from a fit of coughing."

MR. LAWSON TAIT has declared for anti-vivisection and written an essay for his side. Mr. Tait has always appeared, from this side of the Atlantic, to like to do things a little differently from any one else.

THE DEATH-RATE OF MEMPHIS.—The new sewage system at Memphis is said by Colonel Waring to be a complete engineering success. But it has not been possible to apply it to the whole city. The city is much improved, but is still in danger from some insufficiently drained places.

CHICAGO BRUNETTES.—It is rumored that the dark complexion of the Chicago ladies is due to the wide use of nitrate of silver by a popular gynecologist.—*Peoria Medical Monthly.*

TYPHOID FEVER AND TUBERCULAR MENINGITIS.—A differential diagnosis may be made between typhoid fever and tubercular meningitis, by adding nitric acid carefully along the side of a test-tube containing urine. In the former case, several strata are formed, the lowest; a blue ring of indican superposed by a layer of albumen. In the latter, urohæmatin is shown.

INTERMITTENT CHILLS of supposed malarial origin are often due to stricture of the urethra.

IODIDE OF STARCH is an efficient and harmless antidote for most poisons.

COMEDONES are sometimes curable by the application of kaolin four pints, glycerine three pints, and acetic acid two pints. Lemon-juice and acid hydrochlor. dil. are also useful.

SIR ERASMUS WILSON has been suffering for some time from intestinal and bronchial troubles. He is now improving.

OPIUM AND BELLADONNA.—At the late International Medical Congress, Dr. Dujardin-Beaumetz, of Paris, said that since the remarkable experiments performed in England (Dr. Harley's), the doctrine that opium and belladonna were antagonistic, had been abandoned in France.

LARYNGEAL ANÆSTHESIA can easily be produced, according to Rossbach, by injections of half a grain of morphine near the cornua of the hyoid bone, where the superior laryngeal nerve enters the larynx. Ice or ether spray applied here also tend to make the larynx insensible. The utility of this fact in the treatment of spasmodic troubles of the larynx is apparent.

DENTAL TUMOR OF LOWER JAW.—Dr. C. E. Nelson, of this city, reports (*Canada Medical Record*) the case of a girl, aged fifteen, who was suffering from a large tumor of the lower jaw, which had been steadily growing for six months. A prominent surgeon diagnosed the case as syphilitic, and urged its removal at once. Dr. G. P. Miles, dental surgeon, saw the jaw and was convinced that the tumor was caused by several of the second teeth, which had not yet been evolved. Passage of a probe proved this to be the case. The cavity was found and opened, and the patient soon recovered.

DR. A. N. BELL, of New York, the esteemed editor of the *Sanitarian*, republishes in that journal the essay for which he received the Merritt H. Cash prize, in 1864, on "Vaccination."

SUBCUTANEOUS USE OF THE SILVER SALTS.—According to the experiments of Reimer, and late of Jacobi, nitrate of silver, when given as usual in pill form, is decomposed, and does but pass into the blood. It is chemically inactive.

Professor Eulenburg has recently tried the effect of giving certain of the silver salts hypodermically. Silver pyrophosphate is soluble in 3.85 parts of phosphoric acid to 100 parts of water. From ʒ ss. to ʒ jss. of this was injected into rabbits. Some of it produced a local discoloration, but a part passed directly into the blood, and was detected there and in the urine.

This solution and also an albuminate of silver (argent-oxide united with albumen so as to make a solution equal to one per cent. of nitrate of silver) were given subcutaneously to various patients. The dose of the albuminate solution was ½ to 1 c.ctm.

ULTRA-QUININE—A NEW ALKALOID FROM CINCHONA.—This base has recently been separated by W. Geo. Whiffen, and receives its name from its action on polarized light, which it rotates to the left more powerfully than does the sulphate of quinia. There has, as yet, been no attempt to locate it therapeutically. It was obtained from a variety of the bark known as *cinchona cuprea*, and only in small quantities, from one to eight per cent.

CHARCOT'S METHOD OF GIVING BROMIDES IN EPILEPSY.—Charcot begins by giving 3 grains of potas. brom. daily for a week; then 4 grains, 5 grains, and 6 grains, each given daily for a week. This dose must be kept up for four weeks. Then the first dose of three grains is returned to. Such a gradual change in dosage lessens, it is said, the bromide-exanthem and the muscular weakness.

THE FIRST APPEARANCE OF YELLOW FEVER.—The first case of yellow fever this season has recently been found in New Orleans. Its history is instructive. The patient, a young English sailor, had been in Havana a few days. He then shipped on the British steamer, Marco Aurelio, a new iron vessel in excellent sanitary condition, which had gone to Havana simply to discharge a load of cattle, and had not touched shore or shipped a handful of soil. This steamer arrived at New Orleans Quarantine June 14th, and remained there the prescribed time. She was carefully fumigated and every one on board was pronounced healthy. June 21st the Englishman shipped on a Liverpool vessel, slept on it one night, next day was taken sick and June 25th died, of yellow fever.

The case is somewhat similar to one that reached the Presbyterian Hospital, in this city, three summers ago. The only comfortable way to explain them is to suppose they are not really cases of yellow fever.

Original Lectures.

ACUTE SYPHILIS.

A Clinical Lecture

By FESSENDEN N. OTIS, M.D.,

PROFESSOR OF GENITO-URINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

Gentlemen: This man presents the characteristic developments of acute syphilis, and affords us an excellent opportunity to study its leading features. The initial lesion is said to have occurred four months ago, and one month after the suspicious connection. It healed in a couple of weeks. During its presence he says it looked like a simple sore, but there is still here a little knot of induration, indicating the character as well as the locality of the lesion. We find also well-marked enlargement of the lymphatic glands of the groins, and particularly below Poupart's ligament, on both sides, which latter is quite unusual. You also observe very plainly an eruption on the forehead. It is papular in character, and is characteristic of the secondary eruption of syphilis, the first eruption being a roseola, which usually comes on at a period varying from six weeks to two months after the appearance of the initial lesion. Then, after another interval of about the same length of time, we get the second eruption, which is papular in character, the first—the roseola—being macular, and occasionally slightly elevated. The second eruption has been described by authors as of a raw-ham color, or a coppery hue. It is rosy in color when it first makes its appearance, but grows darker and darker, until finally the papule passes away, leaving a distinct reddish or copper-colored stain. You will observe in this patient that the eruption is very prominent and wide-spread over the back. Some of the papules are surrounded by a little exfoliated epidermis, which is known as the "collarette of Biett," and is considered characteristic by some writers. It is simply an exfoliation of the epidermis of the surface of this papule, seen most distinctly at its base, and is dependent upon modified nutrition, caused by infiltration of the papules with cells. These interfere with the vascular supply of the part, and we get the exfoliation here exactly in the same way that we get it at the point of initial lesion—from accumulation and concentration of cells in that locality. When this exfoliation is present on a papule, it affords an additional proof of the syphilitic character of the trouble. You will, however, see cases of psoriasis where the scales have been brushed off, which so nearly simulate the syphilitic papular eruption that it is impossible to distinguish between them; and without any other aid we are often obliged to wait further developments in order to make the diagnosis. Fortunately, however, for the diagnosis, but unfortunately for the patient, we nearly always have, at the time of the occurrence of this papular eruption, other lesions which aid us in making the diagnosis. The glandular enlargements in the groins, of the neck and also in the epitrochlean spaces—sometimes one, sometimes all—ought to be well marked by this time. You will observe here on the neck, a gland which can be seen at quite a distance—it is so much enlarged. There is a group of enlarged and indurated glands just behind the sterno-cleido-mastoid muscle, and another further back on either side. Here in the right epitrochlean space there is an enlarged gland about the size of a large pea, and what I do not remember to have ever found before, viz., another gland about two inches higher up, only a trifle smaller than the first. Quite often the epitrochlean gland, instead of being in the little space above the internal condyle of the humerus, is found an inch or two or three inches higher up, between the borders of the biceps and the triceps; but a supernumerary gland, as in the present instance, is very rare. By this time also papules occur in the mucous membrane, and these are especially characteristic, there being nothing else which resembles them, unless possibly in psoriasis. When syphilitic papules occur in mucous membrane, they usually soon become eroded and covered with a diphtheritic pellicle, to greater or less extent.

Mucous patches—really papules—in the mouth are characteristic of syphilis in its acute stage, and are present in a marked degree in this case. The mouth and the tongue are literally covered with them to an extent which you rarely see. These papules, which appear on the tongue, throat, and mouth, are superficial, and so flat that they are scarcely if at all raised above the surrounding surface or spread over an area varying from the size of a pea to that of half a dollar or larger, having often a gray or pearl colored diphtheritic edge which occasionally festoons the edge of the soft palate, forming a very characteristic and unmistakable mark of syphilis. Some time ago I was called to see a man who was supposed to be suffering from diphtheria. I found him surrounded by his family who were in great solicitude about him. On looking into his throat I saw this characteristic festooning of the palate, and did not hesitate a moment in making up my mind that the trouble was syphilitic. Soon having an opportunity to speak to the young man alone I discovered that he had syphilis, although he had not before been aware of it. The mucous patch is also liable to occur between the toes or any place where there is habitual moisture. Just at the verge of the anus is a favorite seat for it; and knowing this fact, examination of this locality will often help you out in the diagnosis of an obscure case. The mucous papule from its prominence when on the skin or semi-mucous membrane about the anus is usually called a mucous tubercle, and is quite characteristic in this patient, as you see.

You should bear in mind that the secretions of all lesions during this stage of the disease are inoculable, and one suffering from it may communicate the disease from the secretion of any open lesion upon his body or on the mucous membranes. You will understand, therefore, the importance of warning the patient having such lesion of the danger of communicating the disease to others by contact. A pencil, a pipe, a spoon, a knife or other article introduced into the mouth where mucous patches are present, some of this secretion contained in the saliva drying upon it, and afterward coming in contact with an abrasion of the lips of another person, will communicate syphilis to that person as positively and certainly as would a syphilitic venereal connection. From this you may see that syphilis is not necessarily a venereal disease, but any one exposed in the ways above referred to is liable to receive it, in which event it will follow the same course as if acquired by venereal connection. The great security which we all have against the accidental acquirement of syphilis is, that it requires an artificial port of entrance—a fracture of the skin or of the mucous membrane for its inoculation. Otherwise, sooner or later, we

should all be likely to have it, for we could not come in contact with people who have syphilis without danger of getting it at every turn. But, fortunately, it requires an abrasion for its entry, it is rarely through the ordinary affectionate relations between children and parents, brother and sisters that communication of the disease takes place. If, however, an abrasion exist upon the lips of both parties, the disease may be communicated from the one to the other by a kiss. I have often known this to occur in the venereal kiss, but never by the ordinary kiss of courtesy and family affection. But the liability to communicate the poison to an innocent person should be borne in mind by every one passing through the acute stage of syphilis. We must also bear in mind the fact that the disease may be transferred from a syphilitic to an innocent person by the physician, by the use of the spatula, carelessly laying it down after examining a syphilitic mouth, allowing the secretions to dry upon it, then introducing it into the mouth of another patient before properly cleansing it. This is especially liable to occur if the second patient be a child, as by its restlessness during the examination a lesion of the mucous membrane of the mouth may be made by the instrument. All instruments in use about the mouth, throat, or teeth should be carefully cleansed and passed through the flame of an alcohol lamp immediately after use, and certainly before use upon another person, because syphilitic lesions may be present, although unrecognized. Several well-authenticated cases have come under my observation where syphilis has been contracted in the mouth from lack of proper care in this regard. Mucous papules are very often present in the vagina or on the os uteri of females suffering with acute syphilis. In the *Independent Practitioner*, for March of this year, may be found a report of no less than eight cases of syphilis of the finger, in medical men, acquired through vaginal examinations or attendance on syphilitic women during childbirth; and since sending in that report I have seen two similar cases, occurring in the resident medical staff of one of the hospitals of this city. All of these cases were followed by constitutional evidences of syphilis. It is scarcely necessary to say that the early recognition and local treatment of mucous papules, patches, or tubercles, is one of the important duties attaching to the management of acute syphilis. Another characteristic lesion of the disease consists in the presence of scabs in the hair, as seen in this patient. The discovery of scabs in this locality sometimes enables us to make a positive diagnosis, when otherwise we would be in doubt. Falling of the hair, or alopecia, is one of the common, though not constant, concomitants of this stage of the disease, and it is readily accounted for on the same principle that explains the exfoliation of the epidermis in the syphilitic papules. The crowding of newly formed cells in the vicinity of the hair-bulbs interferes with their nutrition. It is not at all unusual for a patient to lose his hair completely, including his eyebrows and whiskers, but this baldness is not permanent, since on proper treatment, directed to the removal of this superfluous cell material, the hair is renewed. We find that any or all of the foregoing lesions of syphilis may be absent and the patient yet go through a disease which shall be recognized as syphilis. In other words, this disease varies in its intensity as much as any other, and except the enlargement of the lymphatic glands none of the conditions which you see in this patient are necessarily essential to the progress of syphilis. This is a very marked case, one in which we find present more than the usual number of characteristic lesions or manifestations.

The treatment of this, as well as all cases of syphilis during the acute stage, will be addressed to the removal of the material which is causing the trouble, that is, to the superfluous cell-growth or accumulation, the same material that we find in the initial lesion, and the same as that which we find embarrassing and enlarging the gland structure, the same as in the papule, the same as in the mucous patch, and the same as in the papules which form the scabs which occur in the hair. These lesions are all brought about and kept up by one and a single condition, namely, that resulting from an abnormal local proliferation and accumulation of germinal cells. This fact has been substantiated by repeated microscopical examinations of all lesions of acute syphilis. Consequently, the cause of all the several conditions or lesions of active syphilis being the same—that is to say, an accumulation of this embarrassing cell material—the treatment is simple, and the same for all, having simply for its object the removal of such material.

The question as to how this shall best be effected leads us to consider first the nature of the material we desire to be rid of. This has been proven beyond a question to consist of human germinal cells, in no known respect different from normal germinal cells, except that they are the product of a proliferation more rapid than that process under normal conditions. Microscopically they cannot be distinguished from the cells which are proliferated and accumulated to repair loss of normal tissue brought about by ordinary causes. Secondly, What are the means and processes by which healthy cell-material, exuded in excess of the necessities of growth and repair is removed? The answer is simply that the necessary process is a fatty metamorphosis, through which alone any living material, normal or abnormal, must pass before it can be eliminated from the living organism. The means by which it may be effected are various: 1st, pressure; 2d, innutrition; 3d, various external agents and internal remedies, which by experiment have been found efficient in producing or hastening fatty degeneration or metamorphosis of tissue.

First, in regard to pressure: The effect of pressure in producing this result is recognized in its known influence as a surgical measure in reducing and dispersing abnormal growths. This is also recognized in its tendency to spontaneous disappearance, after a time without treatment, of the cell accumulations of syphilis. The tendency of all syphilitic lesions is toward recovery. The necessary pressure exerted upon any local cell accumulation in the tissues would tend toward its removal by fatty degeneration.

Second, in regard to innutrition. Withholding of necessary food produces fatty degeneration of the tissues. The starvation cure was at one time, especially in Germany, in great repute as a cure for syphilis. The sweating cure. The long popular and much vaunted cure by cathartics, diuretics, etc., through profuse drinking of decoctions of sarsaparilla, senna, and different woods, can now be recognized as influential through their capacity to hasten fatty metamorphosis. But the remedy of greatest acknowledged value in the treatment and cure of syphilis for the past two hundred years, and up to the present day, is *mercury*, and this it is well known is also the most efficient agent in producing fatty

metamorphosis of living material. Healthy persons quickly emaciate, all kinds of tissues break down, under its continuous excessive use. In the salivation it then produces, the characteristic fœtid odor has been found due to the decomposed fat which results from the fatty degeneration it causes. In point of fact, every remedy which has ever had a substantial reputation as of value in the treatment of syphilis will be recognized *à priori* as one of greater or less power in inducing fatty metamorphosis. If then we find in syphilis, as the characteristic and essential factor of every lesion, an accumulation of superfluous cell material, sufficient in degree to embarrass the functions of the vessels or tissues implicated, we have good reason to introduce the remedy which *par excellence* is known to be potent in removing it, namely, mercury. And if we consider that this remedy is also in highest repute from a clinical standpoint, we are warranted in its administration with the expectation of the best possible results. The manner of its use, the size of the dose, its frequency, and time of continuance, only remain to be settled. Clinical experience in the administration of mercury has taught the fact, now accepted by all recent recognized authorities in matters syphilitic, that small doses of mercury continued for a very long period, say from one to three years, constitute the best treatment for the most efficient and permanent eradication of syphilis from the system of a person afflicted with that disease, and that this applies to any and every form and manifestation of it during the acute stage, which stage may be said to cover a period varying in different cases from one to three years. The hastily generated cell material which has been described as the essential element in the production of the different manifestations of syphilis lacks the healthful vitality to enter effectively into the composition of normal tissues. It is present only as obstructive material, and from its presence as such is already subjected to the mechanical influences which tend toward its dissolution. It may then be accepted as more readily affected by remedial measures calculated to induce fatty metamorphosis of living material than such material generated and developed under normal conditions. Hence, a smaller amount of mercury, for instance, would be necessary to effect its removal from the affected organism than would be required to produce a like effect on healthy tissues. Such an amount then as would cause the speediest removal of the imperfect or syphilitic material, without damaging the healthy constituents of the body, would constitute the highest ideal of an anti-syphilitic treatment. Hence, we can accept from an intelligent and philosophical standpoint the position which has heretofore been only taken from a clinical or empirical view of the matter, viz., *That small doses of mercury long continued constitute the most effective and judicious mode of treatment of syphilis during its active stage.*

Beginning then with small doses, of whatever preparation of mercury we decide to administer, in a given case, we increase the amount until we find the constitution of the patient being affected, evidenced by the presence of softness of the gums or a little red line about them. When that occurs, we know we are getting to a point of affecting the healthy structures of the body, and then the dose is reduced until just that point is reached at which the patient can be carried through without any disturbance of the bowels or of the salivary apparatus. In the case of this patient, then, we should commence by giving small doses of mercury, gradually increasing the quantity until the point of tolerance is reached, and keep it there. Any of the preparations of mercury may be given. We will begin, say, with the proto-iodide, a quarter of a grain, three times a day, for two or three days, or, lest the patient should, as is the case with some, be peculiarly sensitive to the influence of mercury, we may begin by giving only two pills a day, for two or three days, and then add a pill at a time as long as he shows no evidence of disturbance from it, and, when the highest point of tolerance is reached, continue the dose. Sometimes blue mass with iron is used, pills containing two grains of the mass hydrarg. with one grain of the exsiccated sulphate of iron—two to four daily until the desired impression is produced, and continuing, usually, about three per day throughout the desired period. In all these cases I may remark that iron is indicated because the health is usually more or less below par. Therefore, when giving the proto-iodide of mercury, I am also in the habit of giving the dialyzed iron, in doses of ten or fifteen drops, three times a day. The biniodide of mercury may be given in doses of a sixteenth of a grain, or any other of the preparations of mercury may be administered in suitable doses, the object being simply to get the gradual and positive effects of the drug. It may be administered by external means, using a small quantity of mild mercurial ointment, say the size of a filbert, rubbing it in under one knee one night, under the other knee the next morning, under the axilla the next night, and so on, using it night and morning. There have been those advocating the hypodermic use of a solution of the bichloride of mercury, but this is a method of administering it which, while I have used it, I do so no longer, and do not recommend it, finding other quite as efficient and more agreeable ways of introducing mercury into the system. Mercurial baths or fumigations may also be used for the same purpose.

Whatever be the form of mercurial you decide upon employing, your treatment should be conducted according to the principles I have mentioned for all the lesions or manifestations of the acute stage of the disease, whether it be of the skin, of the mucous membrane, or whether it be a syphilitic iritis, an inflammation of the iris (which is caused really by a papule occurring at that point, that is, an accumulation or aggregation of cells). All these conditions or manifestations of syphilis, I repeat, respond to this systematic method of mercurial treatment better than to any other. The open lesions during the acute stage of syphilis, chiefly on mucous membrane, the mucous papules, patches, and tubercles, before alluded to, in addition to constitutional measures, require prompt local treatment, especially on account of the contagious property of their secretion. Daily applications of a strong solution of nitrate of silver—forty to sixty grains to the ounce of water—or a light brushing over with the solid arg. nit. will be found most efficacious in hastening their disappearance. This also applies to ulcerations of the tonsils, which sometimes occur during this stage.

When papules are so situated as to cause annoyance by their unsightliness, as on the face or hands, ung. hyd. præcip. alb. with an equal quantity of cosmoline, or a ten per cent. solution of oleate of mercury with equal part of cosmoline may be used as a daily local application with advantage—in the latter case a few drops of one of the essential oils will render it more agreeable. The diet of the patient should be simple, excluding acids, spices, and highly

spiced food. Tobacco is particularly injurious during the course of this disease, from the fact that both smoking and chewing are liable to produce irritation of the mucous membrane, and when a mucous patch occurs in the mouth it is a very difficult thing to heal while its contact with tobacco is kept up. It is certainly a very great hardship for persons who are addicted to the use of tobacco to give it up; but it is very important that they should do so for the proper and effectual treatment of this disease. In a very interesting note, received not long since from the venerable Professor Willard Parker, in which he spoke of syphilis, I remember he very quaintly said in regard to it, "Some people believe that syphilis is incurable; that is not my belief. When a patient comes to me with syphilis I say to him, do you use tobacco or alcoholic spirits? If he says yes, I say to him, you are possessed of three devils—syphilis, rum, and tobacco; if you will exorcise two of them, R. and T., I will take care of and cure the other; but, if you will not agree with me to give assistance in this way, I will not undertake your case." I would advise you all to make a note of this and remember Dr. Parker's advice. I can assure you it fully coincides with my own opinion, particularly in regard to the "rum": and in regard to the "tobacco" also, when the mucous membrane of the mouth and throat is affected or predisposed to trouble.

The length of time usually required for the complete cure of syphilis will vary in different individuals from one to three years, and during all this time the patient should be under judicious treatment, in accordance with the principles laid down in the case just presented. The steady, gentle influence of the mercurial is required until all abnormal cell-accumulations dependent upon the syphilitic influence have disappeared. When all external evidences of the disease have passed away and the lymphatic glands can no longer be felt, or have returned to the condition in which they were found previous to the constitutional stage of the disease, the treatment may be discontinued, but not before, unless there is some idiosyncrasy in the patient which contra-indicates its use. If the patients are faithful, sensible, and obedient, in by far the largest majority of cases they will pass through the trouble easily and happily to a complete cure. A great weight of experience in the plan of treatment which I have indicated, including that of the most distinguished authorities in Europe and in America, assures us of the truth of this, and that patients do not suffer from the long-continued treatment in any appreciable way, and, further, that in consequence of it they have the greatest and the *only* security of escape from the so-called tertiary, or late lesions—the sequelæ of syphilis.

I am quite aware that there is a great popular prejudice against the use of mercury in syphilis, and this has arisen in great measure from the abuse of the drug in earlier times, but it has been kept up and intensified by quacks, and the ignorant and the unworthy of our profession, who, from causes and motives natural to these classes, refuse to accept the testimony of the learned and experienced authorities who are now in complete accord in this matter in every part of the world. Without a show of evidence or experience entitled to respect, they deny the necessity of the mercurial treatment, and make the pretence that syphilis may be as efficiently and more safely managed without it. They point to cases thus treated apparently well of the disease, and claim them as evidences of the truth of their statements. The very important fact that syphilis, in its acute period, is a self-limited disease, and will pass away with any sort of treatment, or without treatment, is not made apparent. This is the fact, and while we claim and know that a judicious mercurial treatment will hasten the cure of the active lesions and stages of syphilis, it is not on this account that the treatment is considered *essential*. It is because, more than any other known remedy, it prevents the sequelæ of syphilis—the so-called tertiary lesions—which result in destruction of important tissues and organs, vessels and bones. These accidents do not occur in the early or acute stages of syphilis. After the apparent disappearance of syphilis in a few months or a year or so, there comes a deceitful period of perfect health, perhaps. The disease is indeed cured; but in two or three, or ten, or twenty years after, new troubles may arise, no longer contagious as in the past syphilis, but destructive. It is this that causes the really important damage. Deformity, disability of body or brain, or both, and, finally, in some cases, death. It is to avoid the danger, present in every case of syphilis, of such results, that the persistent and judicious use of mercury during the acute period of the disease is most important, and is, as we fully believe and know, absolutely essential. We do not urge the administration of mercurials without a due consideration of the responsibility we take in so doing, without a knowledge of all it has ever done that is objectionable, or ever may do; it is that because without a systematic, judicious mercurial course the patient who has once been a subject of syphilis, in no matter how light a form or how slight or short-lived the manifestation, is in jeopardy every hour, and that nothing but a course of simple mercurial treatment, continued systematically for at least a year, can afford any reliable security. This is the experience of all in our profession who have any title to a respectful hearing, on account of wisdom and experience, and in the present state of our knowledge of this matter it is sufficient to warrant you in insisting upon the necessity of such a course of treatment in every case of syphilis which in the future may present to you for care and treatment.

Do not understand me to say that every case shall be treated in the same manner as to the size of the dose or the mode of administration, and without regard to the physical condition and circumstances. A judicious following of the plan insisted on is necessary—such an amount and such a mode of administration as may be borne without disturbing the digestive apparatus, or materially interfering with the processes of nutrition. As a rule, if the medicine is judiciously administered, the patient will not only not be disturbed, but he will improve in both these respects. How much a more regular and exemplary mode of life which a proper management of syphilis necessitates, has to do with the improved condition, I am not able exactly to state, but it is nevertheless a fact, that most young men are in better health after a judicious course of specific treatment for syphilis than before its acquirement.

I do not wish to be understood that no other medicines are necessary or advisable in any cases of active syphilis. There are idiosyncrasies that must be respected—cases that will not bear the ordinary amount of mercurial without trouble of some sort. These are fortunately rare, but when they present, you must use your ingenuity so to reduce and combine your most excellent remedy that it may be borne. You may alternate it with the iodide of potassium, which is also an agent of much value in bringing about fatty degeneration of living tissue,

or you may, if you can do no better, rely upon this drug in combination with other means and measures which are known to favor fatty degeneration and elimination.

You may meet with cases that will try your temper and your courage—that will call into fullest requisition all your knowledge and your experience and your judgment, and, not least, all your common sense, and yet fail to obtain such a toleration of the mercurial as will enable you to prevent the occurrence of the sequelæ of syphilis. These cases will, however, I am glad to say to you, be rare exceptions, and you may have the assurance of the rule, that such a plan of treatment as I have sketched out for you will be well borne, and will not alone aid you in carrying your patient with comparative equanimity and comfort through the acute stages of this disease, but, what is of infinitely greater importance, you will give him the greatest possible security against an occurrence of the sequelæ or manifestations of so-called chronic or tertiary syphilis.

Original Communications.

A CASE OF DIARRHŒA TUBULARIS,

With Remarks on its Diagnosis, Pathology, and Treatment.[1]

By WM. E. BRANDT, A.M., M.D.,

HANOVER, INDIANA.

Early in September of 1881 I was called to see Mrs. N——, aged thirty-eight, married but childless. She had been under the care of another physician for two weeks without relief. I found her suffering from intermittent attacks of abdominal pain of a colicky character, which lasted from thirty minutes to an hour, and recurred four to six times daily. She also had pruritus vulvæ of an aggravated type. She was of the strumous diathesis, and presented indubitable evidences of scrofula. She denied ever having had syphilis. Mrs. N—— was of the nervous temperament, and for some years past had complained of anomalous pains affecting chiefly the abdomen and back. For some months past her menstrual periods had appeared at intervals of from two to three weeks, instead of a month, as heretofore. I was informed that the first symptom of the present attack consisted of a burning pain in the vagina, accompanied by a profuse discharge resembling that of the "whites." After a thorough examination I was convinced that the vaginitis was non-specific, and that it was probable that the discharge from the vagina was due to membranous dysmenorrhœa. The pulse and temperature did not indicate any febrile movement; in fact, the skin was cool, the circulation languid, and the pulse remained almost, or slightly below, normal during the subsequent six weeks of her illness, most of which time she was confined to her bed. The tongue did not present the characteristic appearance that it usually does in inflammatory affections of the gastric intestinal mucous membrane. On the contrary, the anterior part presented an almost healthy appearance, and only the posterior portion was covered with a light silvery coat. The bowels were reported to be in a normal condition and moving once or twice a day, the stools being healthy and well-formed. The urine was scanty, high colored, and contained considerable vesical mucus, and on cooling deposited a dense lateritious deposit.

I will state, *en passant*, that my patient's husband was a victim of that rare disease which, for the want of a better name, Roubaud called aspermatism and gross dyspermatism, and that in my opinion the pruritus vulvæ was most probably due to this fact; for in coitus it took him fully half an hour to bring on an orgasm and emission. I was more easily led to entertain this belief from the fact that in 1875, when stationed at Fort D. A. Russell, I treated a case of pruritus vulvæ, with reflex gastrodynia as a sequel, which was entirely relieved by temporarily separating the patient from her aspermatic husband, and interdicting all sexual congress. Mrs. N——'s mental state was very unsatisfactory, she being quite irritable, depressed, and having frightful dreams, with mild delirium and spectral illusions, at night. During the intermissions of pain she would brighten up and grow more cheerful, but when the paroxysms recurred she would lose all hope and declare she would never recover. The restlessness would grow worse toward night, inducing insomnia irrespective of the attacks of pain. Dr. Cummings,[1] has drawn a faithful portraiture of the mental state in this disease. He says: "When the affection has been of long duration the mental irritability is very great, and, what is more painful still, the patient's feelings and views are perverted and distorted. It is unnecessary to add that they are miserable in themselves; and where the nature of the affection is unknown to and due allowance not made by their companions and friends, the cause of misery to others. They are quite sensible that they are not what they formerly were—that they are changed for the worse. They feel, moreover, that they have little control over their mental state, and are apt to fall into a condition of great depression and despondency, relieved from time to time by happier feelings, but those of comparatively short duration." After careful and repeated examinations of the stools, and not finding any membranes or excess of mucus therein, I diagnosticated the case as enteralgia due to reflex action, having its *fons et origo* in the sexual organs, and possibly aggravated by malarial influences which were rife in the vicinity at that season.

My patient had been dosed *ad nauseam* with opium, calomel, and whiskey, by her former attendant, which treatment had increased the pre-existing dyspepsia and destroyed what little appetite she had remaining. I at once placed her on milk diet with toast, gave her quiniæ and ignatiæ per os, and morphia sulph. hypodermically. The vaginitis yielded readily to treatment, but the pruritus vulvæ persisted for several weeks, despite the use of a variety of well-approved remedies that were used both locally and internally. I will say that I got better results from the use of Bulkley's chloral and camphor ointment than any thing used. I also applied to the os uteri argenti nitras, hoping that if the malady was reflex in character this treatment would allay the source of irritation as it had done in similar cases reported by Dr. Jones.[2] I also ordered the vagina to be freely douched with warm starch-water several times daily. But I was disappointed in the result of both of these procedures. I increased the dose of quiniæ, as it seemed to be doing

[1] Read before the Kentucky State Medical Society, April 7, 1882.

[2] New York Medical Record, vol. xiii., 1878, p. 448.

good and controlled the seizures to a certain extent, until it produced cinchonism, but still the paroxysms returned at intervals with distressing regularity. Several weeks passed in this way, and the patient was gradually losing all she had gained during the first weeks of treatment, for almost complete anorexia followed these attacks, and little or no food was taken for several days thereafter. I therefore discontinued the quiniæ and substituted liq. potas. arsen. and liquor ferri nitratis; also gave for the nausea and vomiting, bismuth with hydrocyanic and carbolic acids, ox. cerium, etc.; in fact, I rung the changes on all the antispasmodics and astringents, etc., without any permanent relief to my patient. Her stomach and bowels became so extremely sensitive that she could not take the arsenic and iron, even in one-drop doses, without at once inducing diarrhœa with colicky pains. Whenever she had one of these severe seizures I was sent for to administer the morphia, which I always did hypodermically, and it usually required a repetition of several half-grain doses to give relief. It was after one of these attacks that I discovered in the stool portions of tubular membrane several inches in length, combined with a large amount of white gelatiniform mucus. These attacks of abdominal pain simulated exactly the pain and symptoms incident to the passage of biliary calculi, and would deceive the very elect if they did not carefully examine the discharges for membranes. The seat of the greatest pain in tubular diarrhœa is referable to a spot situated a little above the umbilicus, while in hepatic colic the pain is felt in the vicinage of the right hypochrondium, or directly over the liver. The diarrhœtic pain has a griping, burning, lancinating character, and radiates through the abdomen and thorax. The anguish is so great that the patient writhes in agony and rolls from side to side in bed, pressing the hands or a hard substance to the epigastrium, vainly seeking relief. The skin is cool and often bathed in cold sweat; the extremities are cold; excessive emesis almost always accompanies the exacerbations of pain; the pulse is weak and slow, and the temperature slightly below normal. Well-marked jaundice appeared the day after one of these severe seizures. This I ascribed to the presence of gastroduodenal catarrh. During the continuance of this intercurrent affection, the patient had conjunctivitis, with mild photophobia. The icterus, with the concomitant symptoms, after lasting about a week, subsided *pari passu* After one of these attacks the abdomen would remain very sensitive to pressure at one or more tumefied points, and the patient complained of a feeling of soreness and rawness, as if the colon had been denuded of its mucous membrane. Counter irritation over the seat of pain seemed at times to assist in allaying nausea and vomiting, but beyond this did no good, though carried to vesication. I should have stated that for the insomnia I gave chloral hydrate, potas. bromid., and hyoscyamus, but was forced to discontinue the use of all three drugs, as they seemed, especially the two first, to aggravate the dyspepsia, and thereby increase the periodical exacerbations. There was no evidence of proctitis at any period of the case, but, of course, after several loose evacuations there existed severe tenesmus, but there was no blood in the stools.

Flatulent distention of the colon was not a marked feature of the case, yet it was present occasionally. Dyspeptic symptoms were prominent from the beginning to the end of the treatment. The ejecta did not always contain well-formed tubes, but often consisted of a gelatiniform mucus, or of long, worm-like masses resembling entozoa. These discharges were usually very offensive in their character. At other times the evacuations presented a yeast-like appearance, as if they had undergone fermentation and were mixed with lienteric discharges. Dr. Haberson[1] says: "The nervous system in this disease is manifestly not in its full vigor, and the vaso-motor nerve is so sensitive in its sympathetic connections, that when the bowels are acted upon there is often a sense of great prostration produced, or even syncope. In other cases there is general depression almost amounting to melancholia, and there is inability to take active exercise or to grapple with the worry and fatigue of ordinary life. In young women I have frequently found this state of the colon associated with dysmenorrhœa and ovarian irritation. This condition of catarrh of the colon is augmented by hepatic congestion; the inferior mesenteric veins and the hæmorrhoidal veins become distended, and the morbid activity of the mucous membrane is thereby increased. Hæmorrhoids, also, becoming inflamed, transmit irritation continuously upward to the sigmoid flexure and to the colon. I have found this state in ague, in gout, and in diabetes; the habit of using tobacco to excess may also induce it. The condition I have described is widely different from the serous diarrhœa so often observed in disease of the kidney, and although it may be present as the sequel of dysenteric disease and ulceration, it may be quite independent of such changes. It is distinct also from the diarrhœa which accompanies atrophy of the mucous membrane of the small and large intestine, as well as that connected with lardaceous disease of the bowel. As far as this state is constitutional in its character it is relieved by general treatment, but it often assumes a troublesome persistency as a local catarrh."

A month had now elapsed, and my patient had grown very weak and was much emaciated, and, owing to the weakened state of her assimilating organs, was in a very critical condition. I discontinued all drugs except the morphia, which she said she could not live without; gave her ice-cold milk and lime-water, and muriatic acid with pepsin; also teaspoonful doses of old whiskey as often as required. Under this treatment her stomach gradually regained its tone, and I cautiously began the use of Fowler's solution, which, owing to the irritable condition of the stomach, I injected subcutaneously. I also gave Bland's iron pills, one three times a day, and in a week ordered comp. tinct. cinchonæ, fl. ext. serpentaria, fl. ext. colombo, equal parts, in teaspoonful doses. Under this treatment, with a carefully regulated regimen, she began again to improve. According to Leube,[2] *the selection of a suitable diet* should be regarded as probably the most important part of the treatment. All food, therefore, which is difficult of digestion, and the irritating portions of which pass undigested into the colon, such as leguminous vegetables, cheese, cabbage, stringy meat, etc., must be prohibited; so, also, but little bread should be allowed, as Voit's experiments have shown a bread diet increases the solidity of the fæces. Therefore, the best dietary for patients with this disease should consist of albuminous substances of an easily divisible character, *e.g.*, milk, eggs, mutton or beef, also food and broths containing but little

[1] London Lancet, 1868, p. 153.
[2] Ziemssen's Cyclopædia Prac. Med., vol. vii., p. 369.

starch, and the various kinds of mucilaginous substances, such as rice and barley-water, etc. Fatty food should also be interdicted, as it increases the diarrhœa, and not being absorbed, owing to the diminished power of the intestinal villi, is hurried into the colon and there undergoes decomposition.

As the patient gradually convalesced the dose of the liq. potas. arsen. was cautiously increased, but three drops was the maximum dose that could be tolerated per os.

Fowler's solution, tincture of iron, and fl. ext. ignatia was directed to be taken three times daily for three months after leaving her bed, as the disheartening paroxysms recurred several times a week during all that period; though in the intervals she was free from all pain, and enjoyed comparative health. Seven months have now elapsed since she was first attacked, and for the last three there has been no membranous discharge from the bowels, or any of the concomitant pains; the patient has regained her former health, and though the disease is prone to relapse, we indulge the hope that in the present instance it will not. While to the student of medical literature the disease under consideration is well known, yet I am convinced, from the meagre accounts given of it in our systematic text-books on practice, and in our medical journals, that it must be considered a comparatively rare disease. And, moreover, it seems strange that such a painful malady should have been so overlooked by the leaders of our profession. I was surprised in looking over my library to find no mention of the disease in any of the following classic works on the practice of medicine, to wit: Grave's, Trousseau's, Watson's, Tanner's, and Neimeyer's. Wood, Aitken, and Bristowe give meagre and unsatisfactory accounts of the disease; the latter especially fails to grasp the salient points, for he confounds this disease with dysenteric ulceration. Flint, in the earlier editions of his "Practice," overlooked this disease, and in his last edition barely touches upon it. Bartholow, in his excellent work on "Practice," under the head of "Croupous Enteritis," gives us a very graphic description of this disease. Leube, *loc. cit.*, in his monograph in Ziemssen, treats of this disease in a masterly manner. Dr. Hartshorne, in his edition of "Reynolds' System of Medicine" (vol. iii., p. 162), very briefly, but judiciously, recognizes this malady as a distinct affection. I have not been able to find any cases on record in any of our American medical journals, except those reported by Sir James Simpson in the *Boston Medical and Surgical Journal*, 1855, p. 257, and those recorded in the *American Journal of Medical Sciences* for October, 1871, p. 321; July, 1873, p. 103; and January, 1875, p. 103. They all will well repay perusal, especially the very able memoir by that gifted and veteran observer, Da Costa.

Surgeon Woodward,[1] U.S.A., has given such an admirable *résumé* of the pathology of diarrhœa tubularis that I shall quote him *in extenso:* "The disease in question is a form of diarrhœa characterized by the appearance in the stools of membranous substances, which sometimes take the form of simple or branching tubes; a disease which has attracted considerable attention, and has been described under various names, such as diarrhœa tubularis, chronic pseudomembranous gastro enteritis, follicular duodenal and colonic dyspepsia, fibrinous diarrhœa, chronic pellicular inflammation of the intestinal mucous membrane, chronic croup of the intestines, mucous disease of the colon, chronic muco colitis, mucous disease, and membranous enteritis. Of these various appellatives, tubular diarrhœa, proposed by John Mason Good,[1] not only antedates the others, but seems least objectionable as implying no theory whatever. When the membranous substances do not present any trace of tubular form, the designation membranous diarrhœa might be used with propriety. The term membranous enteritis, proposed by Da Costa, *loc. cit.*, is objectionable because it is equally applicable to diphtheritic dysentery.

"Tubular diarrhœa occurs most frequently in hysterical women or in hypochondriacal men, who, after suffering with nervous and dyspeptic troubles or other evidences of ill health for a variable period, become subject to attacks of colicky pains, sometimes accompanied by a hardness or tumefaction of some portion of the abdomen, and followed by the evacuation of the pseudomembranous substances, which come away in shreds or tubes, sometimes in considerable quantity, and usually accompanied or followed by loose feculent, watery, muco-purulent or bloody stools. The evacuation of the membranous matter is followed by relief from abdominal pain and other pressing symptoms, but very frequently this relief is only temporary and other paroxysms ensue at variable intervals. The individual attacks generally last a week or more, and the intervals between them vary from a few weeks to several months in duration. In some of the cases reported but a single paroxysm is recorded; in others the disease seems almost to have been continuous for a considerable period of time. Of the women affected, a number were suffering at the time from some uterine disorder. Clinical and microscopic examination of the membranous matter passed in tubular diarrhœa shows that it is chiefly composed of inspissated mucus, as was originally supposed by Fernelius[2] (who first described this disease). With this a fluid more or less albuminous in character is often mingled, but fibrine is seldom present in any considerable quantity. Dilute acetic acid does not dissolve the membranes or cause them to become swollen or transparent, while they freely dissolve in a solution of caustic potash. Examined with the microscope, they prove to consist of a hyaline or slightly granular matrix, which becomes fibrillated on the addition of dilute acetic acid, from the precipitation of mucine filaments. Scattered through this matrix are a variable number of cells, and of modified forms resulting from the vacuolation and partial decomposition of these elements. It will be observed that the membranes and tubes in the stools of tubular diarrhœa differ greatly even from those membranes and casts in the stools of diphtheritic dysentery, which are composed of the diphtheritic layer alone, without any portion of the necrosed mucous membrane. The former are composed of hyaline, the latter of granular fibrine. There seems to be no reason why shreds and membranes of condensed mucus should not occur in the stools of simple inflammatory dysentery in the early stages of the diphtheritic form, or mingled with other membranes and shreds in the later stages; but in point of fact, when shreds and membranes are found in dysenteric stools they usually prove to consist either of necrosed tissue or of granular

[2] Pathology, Lib. vi., Cap. 9, p. 181. Paris, 1554.

fibrine. Undigested fragments of food, as in lientery, may, in certain cases, simulate the membranous or even the tubular matters described above, but the difference can be detected at once by the microscope." Dr. Powell, of London, in 1820, reported four cases of this disease, all in women, which he termed "A Painful Affection of the Intestinal Canal."[1] The editor of the *Medico Chirurgical Review*, in commenting on these cases, cites Villermé,[2] thus: "The false membranes of the alimentary canal are perfectly similar to those formed in croup. The fragments passed by vomiting or by stool are generally soft, pulpy, and without any appearance of organization. The reagents which concrete albumen render them hard. Sometimes the flakes are considerable, and when developed in water represent entire tubes broken off irregularly at the ends, which have led to the erroneous opinion that they were portions of the mucous membranes of the intestines. I have had occasion to see great quantities of these adventitious membranes passed by stool in the colic of Madrid. They were generally of a gelatinous consistence and enveloped in mucous. One of these exhibited an exact mould of the intestine, being tubular and some inches in length."

The motive which induced me to put this case on record was to call renewed attention to this interesting and painful disease, which, for reasons adduced, probably occurs in practice more frequently than the profession has heretofore supposed, and not being correctly diagnosticated is, therefore, often mistreated. In regard to the diagnosis, I cannot express my thoughts better than by employing Da Costa's earnest and appropriate words when speaking on the same subject: "I wish to insist upon the necessity of inquiring, in every case of anomalous nervous symptoms (particularly when happening in hysterical persons) in which there is any abdominal pain, into the possible existence of the malady we are discussing. Let the patient's attention be directed to the matter, and the stools carefully examined. The prominence of the signs of the disorder of the nervous system may throw those of the digestive apparatus into the shade. I know this from personal observation; and Copeland[3] speaks of an almost singular case of hysteria, amounting occasionally to catalepsy, in which the discharge of the false membranes from the bowels, and sometimes from the uterus, took place. Do cases ever happen, or rather do attacks in cases happen, in which the membranes are not found in the stools, or are scarcely formed, certainly not in a manner and in extent sufficient to be recognized in the fæces? I believe this possible; and in the diagnosis of such cases is only attainable by laying stress on the general grouping of the symptoms and by a process of exclusion. It is, however, greatly facilitated if we have ever seen the patient during a seizure in which the membranous discharge was discernible."

In regard to the therapeutic indications, I have nothing strikingly new to offer. The treatment must be largely symptomatic, as there is no known specific. I believe all that can be done by drugs can be accomplished by the hypodermatic injection of morphia and the internal exhibition of arsenic, iron, and ignatiæ, to be used continuously for some months in chronic cases. *I would also commend the subcutaneous use of Fowler's solution in cases where it cannot be tolerated by the stomach.* If at the beginning or during treatment the bowels should become loaded with irritating fæces, I would use equal parts of ol. ricini and aro. syr. rhei. in sufficient doses to thoroughly evacuate them; but subsequently would mainly rely on enemata to relieve any existing constipation, as I consider cathartics and all forms of mercury used under these circumstances to be very pernicious in their effects. Bartholow, *loc. cit.*, recommends tinctures of nux vomica and physostigma, fifteen to twenty drops of each, *ter in die*, for the subacute and chronic cases. Electricity has been highly lauded by Cummings, *loc. cit.*, and I think it worthy of further trial. Moreover, this opinion seems tenable when we reflect on the important therapeutic rôle the constant current plays in the treatment of nervous vomiting and the vomiting of pregnancy, diseases which in some of their phases are remotely allied to the one under discussion.

I do not wish to be understood as saying that gastric catarrh causes the vomiting of pregnancy; but it doubtless exists in all cases that are protracted. This subject is fully discussed by Dr. Lente in THE MEDICAL RECORD, page 485, 1878, who presents a very convincing array of personal evidence in favor of electricity, and supports it by that great authority, Dr. T. Gaillard Thomas, whom he quotes as saying: "I know of no other therapeutic agent which I esteem so highly for the relief of nausea and vomiting as I do the electric current."

CASES IN PRACTICE.

By E. P. HURD, M.D.,

NEWBURYPORT, MASS.

SUDDEN DEATH AFTER CONFINEMENT.

On Thursday night, May 18, 1882, I was called to obstetrical attendance on Mrs. Mary Phillips, multipara, aged forty. Mrs. P—— had been in good health and spirits previous to labor, and, as her previous accouchements had been easy, expected an easy confinement. The waters had escaped and the os was dilating. There was a lull in the pains, which I improved by taking a nap. I was shortly awoke by the coming on of hard labor and the outcries of my patient. The head was advancing well, and in a few minutes the child was born. The afterbirth followed in a few minutes, a little pressure over the abdomen and traction on the cord being all that was necessary. I adjusted a binder and put dry clothes under the patient. Had not previously taken the pulse, as the patient seemed to be all right. There did not seem to be an excessive amount of blood accompanying the delivery of the placenta. I several times inquired if she was flowing; the reply was in the negative. The womb seemed to be contracting well. While attending to the baby, which was of medium size, Mrs. Phillips raised her head to vomit; she had not previously been nauseated. I saw that she was deathly pale. The pulse was small and rapid, and the extremities cold. A clammy perspiration covered the body. I sprang for the whiskey, which I administered by mouth and subcutaneously, raised the foot of the bed and rubbed the dying woman with hot flannels. It was of no avail; in a few minutes she was a corpse. An autopsy was not allowed, though Dr. Snow, the Medical Examiner, whom I summoned, used his influence with me to procure an autopsy.

Churchill in his "System of Midwifery" gives a number of instances of sudden death after confinement. These cases are generally referred to prolonged syncope. In some of the cases a flaccid or fatty state of the heart was found after death; in others no lesion was discovered sufficient to account for the death. As for the condition which gives rise to this fatal syncope we know little or nothing. It does not depend upon hemorrhage, or the shock of labor, or fear; it sometimes occurs several days after labor and during convalescence. Till better informed, we must regard them as cases of cardiac paralysis, any explanation of which must be hypothetical.[1]

If the above may be regarded as a case of embolus, forming in the left ventricle, and including the aorta, the following case is undoubtedly a typical case of embolism of the pulmonary artery. It occurred in the practice of Dr. George W. Snow, of this city, who has kindly complied with my request to write out a report for THE MEDICAL RECORD. The date of the fatality was immediately subsequent to that of Mrs. Philips, above recorded:

"At 7.30 A.M. May 22, 1882, I was summoned to attend in confinement Mrs. C——, aged forty-five years. Patient had been married thirteen years. First child was born in 1871. No subsequent pregnancy till the last. Mrs. C—— had been quite robust and healthy. I found the membranes ruptured, the os slightly dilated, the vertex presenting. Labor progressed favorably, though slowly. The latter part of the afternoon the head had descended to the perineum. The pains now becoming inefficient, at 5 P.M. I applied the short forceps. The child was delivered with very slight traction. The placenta was expelled in twenty minutes, and the womb contracted well. She complained of after-pains in the night, and the nurse gave her two powders of morphia (one-fourth grain) at intervals of three hours. At 7.30 Tuesday morning, the 23d inst., I found that she was unable to pass her water, and I introduced a catheter and drew off about a quart of clear urine. She expressed herself relieved, and passed a very comfortable forenoon. Pulse 76; skin cool. Did not take the temperature with thermometer. Respiration natural. In the afternoon she began to suffer again from retention of urine, and at 5.30 P.M. I again used the catheter and drew off one and one-half pints. She again expressed herself as feeling very comfortable, and thought that she should have a good night's sleep. At 9 o'clock she told her husband that she had not felt as well for months as she did that evening. Between 9.30 and 10 o'clock she complained to the nurse of a pain or tightness n the chest, and the nurse applied a ginger poultice. In about half an hour she requested to be turned on her side, and the nurse turned her on her left side. Presently the nurse noticed that her breathing was more rapid, and she seemed to be in distress. The husband was immediately summoned, and when he entered the room she said, "I am going." I was called, and reached her bedside at 11 o'clock, when I found her breathing labored and jerky. The pulse was quick and feeble; countenance cyanotic, with an anxious expression. The respiratory acts were now performed with great effort, and were irregular. She was perfectly conscious and realized her situation, and passed away at midnight. Probable cause of death, embolism of pulmonary artery."

[1] Vide Churchill, op cit., p. 527.

PERIODICAL HEMATEMESIS.

Mrs. J. R——, aged forty-six, a resident of this city. This lady has been a patient of mine for twelve years, and is a sufferer from chronic gastric catarrh; at least such is my diagnosis. The salient features of this case are the following: (*a*) Acute attacks of gastritis. These occur once or twice a year; it is now eight months since Mrs. R—— has had a severe attack. She is confined to her bed, with fever of a mild character, has a furred tongue, with tenderness over the stomach, and constipation, and vomits everything (even small quantities of iced drinks) for several days. Then the attack subsides and she resumes her usual health.

(*b*) Occasional attacks of vomiting in the morning and after taking food, and vomiting of blood. There is always much mucus in the vomited matters; the blood is in quantities of from one ounce to four ounces. The latter quantity has never been exceeded.

This vomiting of blood has been periodical for the past nine years; it occurs once a week with singular regularity. Mrs. R—— has precursory warnings of this hematemesis, such as heaviness and fulness in the epigastrium, and headache. She expresses herself as much relieved by the vomiting of blood. The average quantity is four ounces. It is sometimes bright, fresh blood and sometimes clotted.

(*c*) Digestive organs are always in a disordered condition. She lives on dry wheat bread which she soaks in tea; the tea always contains a liberal supply of milk, but no sugar. In fact, saccharine drinks are always avoided. Occasionally a little barley gruel with one-fourth milk is taken. No other food has ever been used, to my knowledge; at least I have her repeated assurances to this effect, and those of her husband and other members of the family. Mrs R—— cannot be persuaded by any considerations to take animal broths or raw eggs, and *I fully believe her assertion that for thirteen years she has not tasted meat:* She has always manifested a strong repugnance toward animal food, and takes (and can take) no spirits, and has only one *penchant* toward alimentary substances that are indigestible—she is very fond of pickles and sour fruits, and has more than once brought on severe vomiting and hematemesis by the ingestion of a small piece of cucumber pickle. Her bowels have always been regular except during the acute attacks above mentioned. The stools are perfectly natural—never clay-colored. There is no particular tenderness over the region of the stomach.

(*d*) Her mode of life is easy and uniform, and she does a great deal of housework. Indeed, till recently she has done all the work for her family, which is small and now consists of only herself and husband. Once a week she has the attack of bleeding from the stomach: she feels oppressed, and suffers from headache, and is obliged to take her bed till the hematemesis passes off. She is now passing the climacteric; has not menstruated for several months; the quantity of blood vomited has been somewhat increased since her menses stopped.

(*e*) She is not *markedly* anæmic, is cheerful and complains very little, though she has a "weak back" and is neuralgic. She is constantly weak and unable to stand any strain or shock. The death of her mother more than a year ago prostrated her for a month or more; a journey in a carriage of two or three miles would be attended with prolonged exhaustion.

I have never been able to detect any hepatic or intestinal trouble, and the heart and circulation are normal.

Mrs. R —— comes from a healthy family without any tendencies to gastric affections. Her mode of life seems always to have been correct. I have no theory to account for the origin of her peculiar infirmities. I do not believe that the principal pathological lesion in this case is relaxation of the stomach. This I affirm after for many years weighing carefully all considerations for and against this supposition. I do not believe that we have here to deal with a case of cirrhosis of the liver, or with cancer of the stomach. The probabilities all point to chronic congestion of the gastric mucous membrane with sanguineous exudation. In fact, this case belongs to what Dr. Lecorchi would define "the hemorrhagic form of chronic gastritis" ("Études Medicales," p. 277, Paris, 1882). Dr. Lecorchi cites a similar case of repeated hematemesis (not, however, periodical, and soon cured) where the gastritis was plainly due to alcoholism. The hemorrhages were regarded as an exudation from the engorged capillaries. In the case of Mrs. R——, the hematemesis certainly seems to be a conservative effort of nature.

Reports of Hospitals.

THE LONDON HOSPITAL, LONDON.

UNDER THE CARE OF DR. SANSOM.

THREE CASES OF ENTERIC FEVER TREATED BY ROTHE'S METHOD WITH FAVORABLE RESULTS.

ROTHE'S method consists in the combined administration of carbolic acid, tincture of iodine, infusion of digitalis, and tincture of aconite in aqueous solution. He relies mainly on the carbolic acid and iodine, which may be therefore said to constitute Rothe's specific treatment. The digitalis he omitted in all cases after the first bottle. Dr. Rothe claims that by this method first the pulse and then the temperature are reduced within from two to seven days. He considers it not to be due to the digitalis, as he did not continue it, nor to the cold wrappings which he used, as they also were only employed during the first few days. In all Rothe's cases this antipyretic action was permanent and all his patients asserted after a few days of this treatment that they felt quite comfortable. A *résumé* of twenty-five cases treated by Dr. C. G. Rothe (nineteen by the carbolic acid and iodine) may be found in the *Deutsche Medicinische Wochenschrift*, Nos. 11 and 12, 1880, by those of our readers who desire further particulars.

Rothe recommended a mixture containing (in one hundred and twenty parts) one part each of carbolic acid, rectified spirit, and tincture of iodine. In Rothe's cases toxic symptoms usually appeared in from two to three weeks.

The following cases were treated on the same plan, but smaller doses were given and the cold spongings more vigorously pushed. It will be observed that toxic symptoms are recorded in none and the results are favorable in all three cases. The record is from notes collated by Dr. C. E. Brunton, House Physician.

CASE I.—Henry F——, carman, aged twenty-nine, was admitted on November 21, 1881. He said his illness had lasted ten days, commencing with a rigor followed by intense headache, shooting pains in the abdomen, and constipation. When admitted he complained mainly of great pain in the head and muscular prostration. Temperature, 104° F.

November 22d.—Is markedly anæmic and appears much prostrated. Is disinclined to talk and appears drowsy. Sordes on lips and teeth. Tongue is red at tip and edges, in centre is dry and brown, and presents transverse cracks. Patient is thirsty and the bowels are confined. There is slight dulness on percussion at the bases of both lungs and the breath-sounds are feebly heard. Breath-sounds harsh at apices. Respirations, 40 per minute. First sound of heart indistinct. Abdomen distended and tympanitic. Tenderness in right iliac fossa. Gurgling questionable. Whole of front of abdomen is covered with a number of small reddish brown spots, apparently the remains of a former rash (syphilitic ?). Amongst these are a few more elevated spots of a lighter red, which disappear on pressure and which may be the ordinary eruption of enteric fever. Edge of liver extends a little below border of ribs. Temperature this morning, 103°. Ordered liquid diet and mist. salinæ. To be sponged every four hours.

November 23d.—Patient about the same. Pain in head principally referred to occipital region, where, on examination, a hard lump, as large as a hazelnut, is found near the occipital protuberance. Front of abdomen and chest now covered with numbers of small reddish brown raised spots, disappearing on pressure. Bowels still confined. Has vomited small quantities of curdled milk once or twice since admission. Temperature remains between 103° and 104°.

every three hours.

Cold sponging and packing every two hours: sponge to be sprinkled with a five per cent. solution of carbolic acid.

In the evening, pulse very feeble and prostration increased. Ordered a drachm of brandy every hour.

November 25th.—Temperature has varied between 102° and 103° during the last twenty-four hours. Has passed one motion, yellow and of pea-soup-like consistence.

November 28th.—Temperature has varied between 103° and 104°. Has passed one motion, not very typical. Patient lies in a half-comatose state, has a little delirium, and is very restless at night. First sound of heart extremely faint, pulse small and feeble. Teeth and lips covered with sordes. Tongue very dry and brown, some deep, transverse cracks. No more vomiting. Successive crops of typical spots on abdomen and chest. Muscular tremor in arms and hands. A slight fall (5° F.) of temperature at 4 P.M.

Ordered to add

Tr. digitalis..... ♏ ij.
Tr. aconiti..... ♏ j.

to each dose of the mixture, and to take a dose every hour. Sponging to be continued the same.

November 29th.—Mixture taken hourly since 6 P.M. yesterday. To-day the highest recorded temperature was at 8 A.M. and was 101.2° and at 8 P.M. 99°, during the day the temperature has been generally below 100°.

Patient seems more intelligent and in less discomfort. Has passed one motion partially formed.

November 30th.—Treatment continued the same, but wine is substituted for the brandy. Temperature normal. First sound of heart stronger, pulse slow, but more regular and beats firmer. Patient has had a very comfortable night, free from delirium and is much "brighter" to-day. Complains of no discomfort whatever, but says he is "hungry." Mouth and tongue cleaner and moister, and all the symptoms have undergone a marked change for the better within the last few days. Packing to be twice a day.

From this date onward the temperature remained at normal, the pulse rapidly regained its normal rate and firmness, and the first sound of the heart regained its tone. No fresh spots after 29th and no return of diarrhœa, the motions being formed and of dark color. Return to health and strength was rapid but steady. The frequency of administration of the mixture was diminished gradually up till December 8th, when a weak quinine mixture was substituted. The patient was finally discharged on January 3, 1882, without having had any unfavorable symptoms whatever during convalescence or any tendency to relapse.

Case II.—Joseph F——, aged nine, was admitted on January 5, 1882. No history could be got from him, but it was supposed that he had been ill nearly a fortnight.

On admission, all the symptoms were well marked. Temperature ranging between 102° and 103°. Face flushed; skin hot; eyes have a dull look; pupils dilated; tongue coated with dirty white fur, red at tip; lips and teeth covered with sordes; throat sore; complains of pain in abdomen about cœcal region; slight gurgling there and tenderness on pressure; bowels confined; liver and spleen not appreciably enlarged; abdomen generally distended and tympanitic; sudamina very abundant; on abdomen and back several rose-colored spots, elevated, and disappearing on pressure; heart's first sound weak; no murmurs heard; pulse rapid (140) and dicrotous; loud crepitations heard at bases of both lungs posteriorly. Some impaired resonance also in that region.

Treatment.—Liquid diet; Rothe's carbolic acid and iodine every two hours. Carbolic sponging every two hours if temperature be 102°.

January 7th.—Temperature rose to 104.2° in the evening (highest temperature during illness).

January 9th.—Temperature remains between 101° and 102°.

Each sponging reduces it one or two degrees. Tongue darker, more cracked on dorsum; general symptoms the same; much headache. From evening of 7th till to-day has moaned much, and complained of great pain in the epigastric region. No vomiting or shivering. Specific treatment stopped *pro tem.*, and pulv. opii., gr. ¼, administered to relieve pain.

January 11th.—Epigastric discomfort much less; temperature, 103° last evening; 100° this morning; pulse still over 120, dicrotic tracing taken to-day; first sound of heart weak; motions liquid.

Muco-crepitant râles very abundant in right front of chest, with tubular breathing. Muco-crepitant râles less marked on left front, with tubular breathing at base. At back, much tubular breathing at left base, with liquid râles.

Specific treatment again commenced. From the 11th to the 13th the temperature fell gradually to normal, and, with the exception of two temporary rises, remained so till recovery. With the fall of temperature there was marked cessation of the other symptoms. Tremors have disappeared, and appetite seemed to return. Tongue cleaner. On the 14th, the chest-sounds were much improved; a few spots still remained on abdomen. Pulse 96. Steady convalescence from this point was the rule, but on January 19th a large number of large inflammatory patches appeared on the left side and on the trunk, extremely painful and tender, and which all suppurated. The patient left for the country on February 15th in fair health and strength, and with the chest signs all cleared up.

Case III.—Isaac L——, aged twenty, was admitted on February 2, 1882. Could not state how long he had been ill.

Face slightly flushed. Pupils dilated. Sordes on lips and teeth. Tongue coated with white fur, red at tip and edges. Lies on his back. Abdomen distended and tympanitic. Tenderness in right iliac fossa and at epigastrium. No gurgling. Says he has had diarrhœa during the last few days. To-day passed but one motion, very typical. About forty reddish spots on abdomen and trunk. First sound of heart weak. Pulse 104, feeble and dicrotous. Breath-sounds normal. Temperature between 103° and 104°. Complains of feeling weak and sick. Has had much headache, but none now. Rothe's treatment was ordered—a dose of the mixture to be given every two hours and the patient to be sponged with carbolized water whenever the temperature rises above 102°.

After the first sponging the temperature fell a degree (from 103.2° to 102.2°). It afterward rose to 103.4° in the cour e of the night, but a second sponging reduced it to 101°. It again rose in the afternoon of the 3d, reaching 104° at 4 P.M. (the highest temperature recorded during the patient's stay in the hospital).

February 4th.—Tongue getting brown. Complains of pain in umbilical region. Marked muscular tremor. Dicrotic pulse. Rhonchi heard at the bases of both lungs, but no dulness on percussion. Temperature at 8 A.M. 102.2°; at 12 P.M. 103°.

February 7th.—No abdominal pain now. Increased area of splenic dulness. More sleep last night. Not so delirious to-day. Temperature, 103°. First sound of heart heard better. Pulse very dicrotous.

February 11th.—Has had no delirium during last few days but has been very sleepy. Tongue no longer brown, much clearer. Slight muscular tremors still. Temperature 100°.

February 13th.—Bowels constipated for six days. Still a few faint spots on abdomen. Tongue clearing. Patient "feels hungry." Still sleeps very much. Temperature normal.

February 17.—Temperature sub-normal. Pulse slow and tranquil. No dicrotism perceptible. One or two spots still on abdomen. Tongue now grayish white, not coated. Motions formed. Appetite good.

February 21st.—Still convalescing very favorably.

Remarks (by Dr. Sansom). For more than sixteen years I have adopted the plan of internal administration of an antiseptic agent in the treatment of most of the zymotic diseases. The agents I have usually employed have been the sulphite and sulphocarbolate of sodium. In scarlet fever and diphtheria experience has been extraordinary favorable. In typhoid fever, however, I have hesitated, from the fear that the administration of a saline capable of transformation into the sulphate of sodium might

possibly aggravate the tendency to diarrhœa existing in the disease. The plan of cold sponging and bathing, which came to us from Germany, I have adopted with what I consider to be favorable results. It is to be recollected, however, that the cases which come under our treatment in the hospital are usually very unpromising cases—they are often feeble, ill-nourished persons and the disease has long progressed without treatment. Our results, therefore, from the cold bath treatment alone are not so favorable as those recorded by our German contemporaries. Dr. Rothe's treatment, in addition to the cold treatment, has been founded on those antiseptic principles which I have so long advocated (*vide* "The Antiseptic System," London, Churchills, 1871). He supposes that the combustion of the carbolic acid and iodine enhances the germicide qualities of each. The question has to be decided by experience. The cases here recorded were of exceptional severity; the results, so far, seem to be singularly favorable.

Progress of Medical Science.

Farinaceous Infant Foods.—Under the above title Dr. George B. Fowler publishes in *The American Journal of Obstetrics and Diseases of Women and Children*, vol. xv., No. 2, April, 1882, an inquiry into the chemical composition of the principal prepared foods for infants now found in the market. Dr. Fowler states that he was impelled to undertake the critical examination of some of these preparations on account of the importance of discovering as perfect a substitute as possible for mother's milk, because of the frequency with which we are compelled to employ these foods, and on account of the conflicting experience of the profession regarding their relative utility. He specially emphasizes the fact "that simple microscopic inspection, unaided by chemical means and physical processes, is wholly unreliable and inadequate in determining the composition and nutritive worth of these farinaceous compounds." Dr. Fowler begins the discussion of his subject by alluding to the relative nutritive values of the various grains employed in the preparation of the foods in question, with a view to forming an approximate estimate of the relative proportions in which each should be employed. This basis for a scientific discussion of the subject is founded upon the important physiological fact that, to fully subserve the purposes of natural nutrition, foods must contain albuminoids, hydro-carbons, and mineral matters in proper proportion. Since the proportion in human milk, the natural food for infants, between the albuminoid and non-albuminoid ingredients is as 1 to 2.95, it is just to assume that the same relations should obtain in the artificially prepared aliment. These data would seem to justify our belief that the most desirable substitute for human milk may eventually be synthetically compounded. No elementary food product, however easily digested when employed alone, is sufficient for the maintenance of health or even of life. By proper processes it is, however, possible to vary the relative proportions of constituents in flour produced from any grain by the admixture of flour from other cereals. In this way a food sufficient for prolonged normal nutrition may be prepared. Dr. Fowler next formulates the leading facts relating to the structure of different cereal seeds, and states the chief microscopical features of gluten, starch, dextrine, and other ingredients of foods obtained from this source. The author then gives the results obtained by chemical and microscopical examinations of the various foods of the shops. Their names are mostly familiar. The chief ones are Horlick's Food; Imperial Granum; Ridge's Food; Nestle's Milk Food; Anglo-Swiss Milk Food. Dr. Fowler shows that the actual composition of many of these preparations does not at all correspond with the published statements concerning them. He does not, however, attempt to decide which of the foods is best adapted to the wants of infants, but leaves this question to be settled by practical experiments based upon chemical and microscopical examinations such as he has conducted.

The Abortive Treatment of Buboes and Lymphadenitis Generally by Carbolic Acid Injection.—Dr. Morse K. Taylor, U.S.A., presents a paper on this subject (*Amer. Jour. Med. Sci.*, April, 1882). By abortive he means the immediate and complete arrest of inflammation in the gland, whatever be the cause giving rise thereto; also the prompt and permanent relief of pain, and the prevention of the formation of pus and abscess. An experience of seven years, during which time Dr. Taylor has treated nearly one hundred and fifty cases of various forms of lymphadenitis, both specific and non-specific, has led him to eschew all other forms of treatment and to rely entirely on the injection of carbolic acid. In the cases treated, where they came under treatment before the formation of pus, he states that he has not failed to arrest the process of inflammation immediately and allay the pain in a few minutes by the injection of his standard solution, eight grains to the ounce, of which twenty to thirty minims will be found sufficient. When pus has formed he evacuates it by aspiration unless the abscess is of large size, in which case only a part of the pus should be withdrawn, and a sufficient amount of the solution thrown in to fill its place.

Dr. Taylor states that the carbolic acid treatment gives equally good results in cases where there has been spontaneous opening. The abscess should be washed out, and compression, either by weights or tight bandaging, applied. He advises the use of the ether spray to diminish the sensibility of the part before giving the injection. Care should be taken to reach the centre of the tumor. To this end he lays down the rule that two-thirds of the narrowest diameter of the tumor will indicate the depth to which the needle should be thrust. Dr. Taylor states that the average time his patients have been deterred from their usual employment has been three or four days, and many have pursued their avocation without interruption. As regards the *rationale* of the treatment, Dr. Taylor, accepting the views advanced in the late International Medical Congress, that lymphadenitis is the result of septic absorption from neighboring parts, considers that the anæsthetic action of carbolic acid plays an equally important part with its antiseptic action. The paper is accompanied with the history of twenty cases successfully treated with injections of carbolic acid.

Fatal Cases of Pleuritic Effusion from Failure to Perform Thoracic Paracentesis.—Dr. Henry J. Bowditch, of Boston, whose name is associated with the introduction of an operation that has been successfully performed the world over in a very large

number of instances, now cites two cases where he charges the death of the patient to neglect in one, and delay in the other, in removing an effusion that eventually caused death. One concerned an American student of medicine, treated by a local practitioner in Germany. The patient, though of tuberculous ancestry and personally delicate, had usually enjoyed good health. For six months prior to the last attack, however, he had undergone much affliction of a domestic nature, and his health had been undermined. A severe naso-pharyngeal catarrh was the first bad symptom, and then ensued dyspnœa, lassitude, quick pulse, and rise in temperature, until on the fourteenth day the thermometer registered 104.8° F. Physical examination revealed dulness on percussion over the left lung, below a horizontal line falling one inch below the nipple; bronchial breathing over this area of dulness and roughened breathing above. Apex beat to the right of the normal. An occasional râle and a slight friction sound near the spine, posteriorly. Twenty-four hours later the effusion had reached a point one inch below the clavicle. All this time the treatment ordered had been cupping [wet and dry], calomel to keep the bowels constantly loose, and a restricted diet. An intimate friend, also a medical student, made bold to suggest "tapping" the chest, but was quickly silenced with the remark that it was "too early to think of that operation." The patient gradually became worse, while the attending physician expressed himself satisfied with the progress of the case. Finally, in preparing for a dejection, collapse ensued and he died.

Dr. B., in commenting upon this narrative, maintains his firm conviction that, had tapping of the chest been resorted to on the second day of the increased effusion, and the patient at the same time placed upon a nutritious and tonic diet, with the local use of some mild irritant, such as tincture of iodine to the skin, a different result might fairly have been expected. In the second history cited, Dr. B. was called as consultant to see a little child that had suffered some days from a large effusion. Paracentesis was recommended by Dr. B., but objected to by the attending physician, and a respite desired. On the following day while arguing again as to the medical propriety of the operation, both physicians were suddenly called into the sick chamber to see the little child draw its last breath.—*Boston Medical and Surgical Journal*, January 19, 1882.

Transportation of Diphtheria by the Wind.—It is quite time for us to have some new contribution to the ever-absorbing subject of diphtheria, and this time it comes from an English source. In a paper read before the Epidemiological Society of London, an account is given of a theory by which the propagation of the disease in certain districts is accounted for by the agency of the wind. Dr. Hubert Airy's theory, which has such an amusing but direct relation with his name, is by no means unsubstantial or fanciful. It is based on some thirty epidemics that have been carefully looked into, and where the origin of the disease could be accounted for by the aërial hypothesis. Accordingly, greater force is given to ideas that have never gained widespread acceptance. Particular stress is laid upon a case seen jointly by the author and Mr. Wynter Blyth, where in an outbreak of diphtheria, occurring at an isolated farm-house in North Devon, no clue could be found to its origin other than through the above hypothesis, based on the fact that the wind had blown with unusual force for four or five days before the outbreak, from the southwest, in which direction it was subsequently found that a death had taken place from diphtheria. The same thing occurred at another isolated farm-house on a spur of Ashdown Forest, after the wind had been blowing from the Tunbridge District, where there had been much fatal diphtheria. The disease subsequently appeared on two hills to leeward, without any traceable personal communication. Other cases are taken from Mr. Blyth's paper on "The Prevention and Propagation of Diphtheria" (*Sanitary Record*, May, 1880). Dr. Slade King's "Notes on the Spread of Diphtheria" ("Report of Meeting at Sanitary Institute," Exeter, 1880), and a case published in the Medical Record (January 22, 1881). Interesting studies have been made in the velocity of the wind that determines aërial propagation. Taking as a basis of investigation thirty outbreaks published in a previous paper ("Trans. of the Internat. Med. Cong.," 1881), he finds that, by estimating the mean velocity of the wind for the whole number during the two weeks preceding the outbreak, there was a velocity above the average in the five days immediately preceding, and that it blew from points of infection. Arbitrary isolated points were also selected, and the theory being applied was found to be sustained. If, he urges, the hypothesis of aërial infection is successfully applied to ague and hay-fever, why not to diphtheria? Dr. A. is hopeful that, with the increase in the number of observed epidemics, there will be corresponding gain in corroborative proof.—*British Medical Journal*, April 1, 1882.

Sulphide of Calcium as an Antisuppurative.—Dr. Andrew H. Smith, Chairman of the Committee on Restoratives of the Therapeutical Society of New York, furnishes to the *New York Medical Journal and Obstetrical Review* for June, 1882, a report of the committee on the use of sulphide of calcium for the purpose of preventing or diminishing suppuration. After giving the experience of several members of the society, Dr. Smith concludes his report as follows: Judging from this limited number of cases, it would seem that we are warranted in concluding that in many cases of suppurative affections, ranging from the small pustules of acne to extensive suppurating surfaces, an appreciable, and often a very marked, benefit is derived from the use of calcium sulphide; suppuration which would otherwise take place being averted, or the quantity and duration of an existing discharge being lessened. At the same time its action is not uniform; and in many apparently favorable cases it will fail entirely. The drug is somewhat prone to irritate the stomach, and this circumstance affords an indication for small doses frequently repeated instead of larger ones at longer intervals. One-tenth of a grain every two hours, in acute cases, will generally secure the full therapeutical action of the drug, but larger doses may sometimes be required, and some patients will bear well a grain three or four times a day. Even in small doses the sulphide will occasionally produce headache, and the patient is usually more or less annoyed by eructation of sulphuretted hydrogen.

Iodoform in Tubercular Meningitis.—Professors Moleschott, Coesfeld, and recently Bauer, have reported cases of tubercular meningitis "cured" by the use of iodoform.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 8, 1882.

SOME FACTS ABOUT PATENT MEDICINES.

THE manufacture and sale of patent medicines has become a very important element in the business of the country. It is a question whether the money expended upon proprietary mixtures does not greatly exceed that paid for medical services. It may, perhaps, at first glance, excite a certain feeling of sadness in the doctor's mind to think that millions of dollars are thus turned away from their legitimate channels. But the public is, on the whole, rather the more hurt. Medicine is a thing of which the more there is taken the more there is wanted. People who buy patent medicines, in time drift into the doctor's hand. This may be considered as very generally the rule.

But whatever the evil or the blame, the patent medicine trade exists and flourishes. It may and should be reprobated. But occasionally we may also look at it from other than a critical and aggressive point of view. There are many facts regarding the business which have a certain general interest. The history of the origin, development, decline and decrease of certain patent medicines will furnish study to the psychologist as well as to the medical man.

The patent medicine often develops out of some happy prescription of the doctor. Oftener, however, the disease to be cured is selected first, and then the mixture compounded. This disease, however, must be a widely prevalent one. There are, for example, two thousand different corn-cures for sale by the druggists of the country. Among five thousand different articles in one wholesale establishment in this city there are three hundred and twelve pills for constipation and biliousness; also, in the same collection, about two hundred hair-restorers. The cures for rheumatism, and for coughs, colds, and consumption, are about equally numerous, if we may trust an account given in the *Times*. Bitters are also very popular, because they not only cure disease, but appeal to the appetite for alcohol. We note the presence of one hundred and six different varieties among the five thousand referred to.

The right kind of medicine being selected, the first thing to be done is to advertise it. It is admitted that no industry depends so much upon advertising as does that of patent medicines. Here, indeed, is where the business is shown in its most lurid aspect. The genius of the doctor is exercised in compounding his mixture, that of the patent medicine man in telling what it will do. We are told that the moment a new drug ceases to be advertised the demand for it fails. If, after judicious advertising for ten years, the advertisement is stopped, the demand falls about seventy-five per cent. There will then continue for several years a steady call for the drug equalling about twenty-five per cent. of that which originally existed.

The greed of money is at the root of patent medicine failure. The proprietor wants to make his medicine at less cost, and after a while puts in cheaper ingredients. The mixture which costs fifteen cents, and sells for a dollar, is finally made for five cents: there is a little drop in the amount of advertisement, and the demand ceases.

It is not necessary that a mixture have any medicinal power in order to be widely sold. Those who have ever heard of the "Metaphysical Institute" of this city and "Poor Richard's Eye Water" can testify to a remarkable illustration of this fact.

The geographical distribution of the patent medicine trade would be worth some study. Patent medicines invade new countries. In these countries they flourish most where the heart is warm and trustful, the intellect not so well disciplined. The sunny South spends much lucre upon these goods. Some of the public prints are as rank with specifics as our best religious weeklies. In portions of the great West the trade is also particularly prosperous. There is no reproach to be attached to this fact. It is simply a matter of circumstance, of development. As a man becomes more hard-headed he buys less medicine.

Patent medicines will always exist by virtue of the weaknesses of the human mind. Man is sick; he wants to live; he sees a statement that such a medicine will surely cure him. He half believes it, entirely hopes it, and buys the bottle.

SUCCESS IN PRACTICE.

IF the purely selfish man has any real happiness in this world, it must be in the contemplation that he is so much better off than many of his kind. With him there is a complacency in his contemplation of the struggles and non-success of others which is proportionate in degree to the consciousness of his own ease and prosperity. Some men, comfortably housed during a storm, derive an extra warmth from their fire

in the thought that the tide-tossed mariner may at that moment be freezing, or some luckless wanderer, hungry and alone, may be longing for the shelter of a shed. It is not impossible, also, that the same comparisons are often made in other degrees and in somewhat different ways by the successful metropolitan practitioner, who, while rolling in his well-equipped coupé, smilingly glances at the fresh and virgin sign of the young doctor commencing practice. There is such an apparent gulf between them that there is a bewitching pleasure in trying to imagine how utterly miserable the youngster may be, how poor his present prospects are, and what may be the chances of his ultimate success. While he may, with becoming good wishes for the struggler, hope he is aiming for the top, he is quite certain that for the present he is within very easy range of the ill-luck that overtakes the hindermost. And yet we must not judge the successful man too harshly. He may pity the fresh aspirant with sincerity, and yet he may not be able to help him. If the truth can be confidentially spoken, the successful man has no good practice to spare.

A college professor, who, above all others, should strain a point to help aspiring genius, very properly and frankly confessed this to a graduate who was bold enough to ask for aid. That young man is not now laying on his oars waiting for a tow, but has come to a realizing sense of what is meant by paddling for himself. Let us hope that he may not grow faint by the way, and that he may in the end be rewarded. But the struggle in any event must be a patient and weary one, even for those who are determined to help themselves. Unless a young graduate is fortunate enough to find some community which is not already crowded with doctors, and keeps the matter a strict secret from all his medical friends for a year or two, he must be in the attitude of a privileged intruder upon ground previously occupied by members of his craft.

Thanks to the colleges, this supply is constantly kept up, and the young medical man need not be disturbed in his conscience that the people have to suffer for want of medical aid while he is forced to be idle. The realization of this state of things offsets a commendable pity for suffering humanity in which he should indulge and leaves him free for working out his success in the ordinary way of sowing the seed, harrowing the ground, and waiting for the crop.

We are so often asked concerning professional prospects by young men starting out in practice that we offer this as a general answer. It does not make much difference where he settles. Every place is full. The city is perhaps the best place, if the young man can meet his outgo long enough to obtain an income. Everything depends upon his waiting ability. Country practice gives quicker returns, but, all other things being equal, is less profitable in the end, that is from the mere pecuniary standpoint. The best starts are always made in general practice, and the most successful specialists have always been the most thorough general practitioners. But at the bottom of all is honest, patient, and stubborn work. Every one has the opportunity for using this lever, but comparatively few take hold of the right end.

THE AUTOPSY UPON THE BODY OF GUITEAU.

We have the pleasure of presenting to our readers the fullest and most authentic report as yet obtainable of the autopsy held upon the body of Guiteau.

It is already known that the arrangements for the examination were deficient in many respects, owing either to lack of opportunity or of knowledge on the part of those directly responsible. With every wish, no doubt, for the contrary, there was an utter failure to arrange for a thorough and scientific study of the brain. We would not deprecate the value of our correspondents' work, however. All the facts of scientific value, and they are many, that could be gleamed between the tumbling of the brain into a grocer's scales and the final distribution of fragments are presented here by them.

We learn that the membranes were slightly diseased. This disease was of a character which indicated nothing regarding Guiteau's insanity.

As to the brain itself, and its convolutions, there was a high degree of fissural ornamentation, a well-marked asymmetry of fissural arrangement on the two hemispheres, and an absence of the confluent fissural type. There was a well-marked fissural and general development of the frontal lobes. These also, we are told, had a peculiar shape. There was no gross evidence of disease anywhere in the brain-tissue. It is not at all likely that the microscope could have revealed anything. Under the unfortunate plan of unsystematically cutting the brain in pieces, hardly anything can be expected from the microscope now.

On the whole, therefore, the evidence gathered by Drs. Morton and Dana shows that the brain had probably no detectable disease, that it had a somewhat peculiar fissural arrangement, and that it was of rather a high type. The cause of Guiteau's morbid mental state lay in structural or chemical deviations too delicate for detection with our present knowledge.

"GLOU-GLOU PLEURAL."

In the *Révue de Médicine* for May is an article by Dr. Variot, interne in the service of the late Dr. Raynaud at "La Charité," upon a new auscultatory sound heard in certain effusions of the pleural cavity. As this sound has a pathognomonic value, and should also be of easy recognition, we give a synopsis of its discovery and mode of production: Accidentally a patient with mixed effusion in the pleural

cavity, while making movements of flexions and extensions of the trunk, was auscultated, and a sound designated by Dr. Raynaud as "glou-glou pleural" was heard (sound given forth by a bottle decanted of liquid and air entering). This was subsequently confirmed by Drs. Desnos, Laboulbène, and Damaschino upon the same and a second patient then in hospital. Although the term glou-glou is a neologism, Dr. Raynaud thought it adapted itself so correctly to the phenomenon that it would be difficult to replace it. Besides, it would not lead to confusion. The word "gargouillement," besides being less exact, recalls certain cavity sounds met in purely liquid effusions. Passing over the detailed narration of the cases in which the sound was discovered, we notice the circumstances under which the sound is produced.

Both patients in whom it was noticed had pleuritic effusions, which had lasted some time. In both it was supposed there was some gas from fistulous opening in connection with the effusion. Aside, however, from an almost complete absence of the vesicular murmur for a space above the zone of flatness, there were no signs to make the presence of gas presumptive. Nor were there any of the physical signs of pneumothorax. In order to provoke the glou-glou sound, cause the persons to sit or stand, flex the body at right angles to the lower extremities, and rise suddenly from this position. No sound is heard during flexion, or while in that position; during the act of erection, the peculiar sound, similar to the entrance of air in a bottle being emptied, is heard.

Even palpation by the hand, placed behind on the affected side, can detect a sort of interrupted rolling.

Auscultation, however, practised at this time, enables one to differentiate the glou-glou from all other sounds; three, four, or five large bulles are heard, the rapidity of succession depending upon the rapidity of assuming the upright position.

No autopsy having been made in the cases noticed, the mechanism of the sound is hypothetical. The problem can, however, be simply stated. How is it that, in certain mixed pleural effusions where the quantity of gas is too small to give the signs of pneumothorax, you can provoke the "bulles bruits" by flexing and extending the trunk? We answer, these phenomena are due to the reciprocal displacement of gas and liquids. A flat tone when erect becomes sonorous when bent at right angles. This, however, is a condition observed in ordinary pneumothorax.

It requires, then, special anatomical conditions; those which appear the most probable are those which result from a banded pleurisy. This is the more readily assumed, because in the two cases under observation the effusion was already somewhat chronic. The development of new membranes, more or less thick, is the rule under these circumstances, and adhesions, irregular bands, can subdivide the cavity into little pouches. In the upright position, the gas would occupy the upper compartments; in the flexed, the liquid those previously occupied by gas. If these compartments communicate by restricted orifices, we have a sufficient explanation of the large "bulles" which break when the fluid and gas reciprocally traverse these restrictions.

Its diagnostic value must yet be determined. In the cases mentioned, other signs of pneumothorax failed—neither the "amphoric souffle," "metallic tinkling," nor "fluctuation thoracic," were present. The "glou-glou pleural" was, then, a precious sign when the others were absent.

Reports of Societies.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, March 28, 1882.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

LOCAL TREATMENT OF CARBUNCLE.

DR. A. C. POST presented a patient who came to him with a large carbuncle upon the back of his neck. It had been imperfectly opened and the disease was progressing. A large quantity of disintegrating cellular tissue presented itself at a number of points. He extended the incisions, dividing the outermost edges freely, applied a stimulating dressing with immediate benefit. Considerable arterial hemorrhage occurred from the edges and bottom of the carbuncle when divided, but it soon subsided. The stimulant dressing consisted of basilicon ointment (ceratum resinæ) *two* parts, and oil of turpentine *one* part.

LUMBAR COLOTOMY.

Dr. Post also presented a patient upon whom he performed lumbar colotomy a little more than three years ago. Several years before coming under his care the man suffered from dysentery which became chronic, and the rectum, having been studded with ulcers, became so contracted that every evacuation from the bowels was attended by intense suffering. Efforts had been made to relieve him by making various topical applications, but without benefit. For a considerable time after the operation, the evacuations from the bowels took place almost exclusively from the artificial anus, and the ulcers in the rectum healed. When the healing was complete Dr. Post began to dilate the rectum, gradually increasing the size of the bougie. Finally, a portion of the contents of the intestine passed through the natural channel, and for many months the alvine evacuations had almost entirely passed through the rectum. Twice a month he introduced a flexible rubber bougie, 58 millimetres in circumference, and the fecal mass discharged was of about the same size. Fæces passed through the artificial opening only when the patient had diarrhœa. Gas occasionally escaped through the artificial anus. Dr. Post

thought it was prudent to continue the introduction of the bougie in order to guard against the tendency of the intestine to contract.

INGUINAL ENTEROTOMY.

Dr. H. B. Sands presented a patient with the following history. The man, fifty-eight years of age, whom he saw for the first time in November, 1881, in Harlem, in consultation with Dr. Hays, had been declining in health for five months, his chief symptoms being constipation, dull abdominal pain, and loss of appetite. Dr. Sands' attention was directed especially to a deep-seated swelling in the umbilical region to the left of the median line, which was firm and tender, it giving him the impression that the enlargement might be due to the existence of a morbid growth. A suspicion, however, that it was an abscess, was confirmed after the lapse of a few weeks; and early in December he made an incision about one inch long, and a little to the left of and below the umbilicus, which allowed the escape of a large quantity of fæces, gas, and pus. From this opening and two others, one formed spontaneously, and the other made with the knife, almost all the fæces discharged for three months, and during this period, the patient was, at times, exceedingly ill. After about three months the discharge from the openings ceased, so that three weeks later the abdomen was much distended, neither fæces nor flatus passed by the anus, and the patient presented the usual symptoms of chronic intestinal obstruction.

Dr. Sands saw no way of affording relief except by making an artificial anus, and on the 6th of March, 1882, he established one in the right groin. He did not perform lumbar colotomy, because he did not know the site of the obstruction, and suspected that it might be in the small intestine. The abdomen was distended, the peristaltic movements of the intestines could be seen through the abdominal walls, there was nausea, and the stomach was unable to retain food.

He made the usual incision upon the right side, two inches in length, opposite the spine of the ilium and parallel with Poupart's ligament, and exposed and opened the peritoneum without difficulty. When the opening had been made, two pieces of intestine presented themselves, one of which was larger and more distended than the other, and was the one selected in which to make the opening. From its size, position, comparative immobility, and the fact that it seemed to be adherent to the posterior wall of the abdomen, he thought it might be the cæcum. The artificial anus was established according to the plan of Max Müller, in which, before fastening the intestine in the opening made in the abdominal wall, the parietal peritoneum is drawn forward and united to the edges of the wound in the integument by numerous points of the interrupted suture. By adopting this expedient, adhesion is favored between the parietal and visceral peritoneum, in the neighborhood of the artificial anus, and the danger of fecal infiltration of the muscular and connective tissues is obviated.

About eight stitches of carbolized silk were afterward introduced to secure the intestine in the abdominal wound, and the patient was left for forty-eight hours to allow the formation of adhesions between the opposed serous surfaces. No accident either attended or followed the operation. The adhesions, being firm at the end of forty-eight hours, the operation was completed by making an opening in the gut, one-third of an inch in length, and parallel with the margins of the first incision. The opening of the intestine was followed by a copious and continued flow, for several hours, of semi-solid fæces, which contained a considerable number of orange seeds and lemon seeds. No other foreign bodies were found. The improvement in the general condition of the patient from that time was steady. He was entirely relieved of the distressing symptoms, gained in flesh and strength, and his color and appetite improved. Meanwhile, no discharge took place through the natural anus until day before yesterday, when the patient had a natural evacuation. The mass of fæces was considerable, nearly cylindrical in shape, and about half an inch in diameter. No diagnosis had been made as to the seat or nature of the obstruction; but it seemed pretty clear that it was not due to a morbid growth. The opening, one-third of an inch in length in the intestine, had proved to be inadequate, and distention of the abdomen recurred, so that it became necessary a week ago to enlarge the opening sufficiently to admit the little finger. The result in this case was somewhat different from that observed after lumbar colotomy, in which recovery is usually much less rapid. Dr. Sands thought that the artificial opening could be occluded by a truss.

Dr. Stimson remarked that it was exceedingly difficult to adjust a truss in such cases. With regard to Dr. Sands' statement concerning the prompt recovery of the patient, it coincided with his experience in *three* cases of inguinal colotomy. There was no reaction from the operation, and no serious trouble afterward. In one case, the patient still living, there is more or less escape of liquid fæces from the artificial opening.

Dr. Post remarked that, in comparing the operation in the lumbar region with that in the inguinal region, there were two important considerations. In the first place, which is the most dangerous to life? That has not yet been shown clearly. Opening the peritoneum had been the great bugbear of surgeons, but by ovariotomists it had come to be regarded as a procedure unattended by special danger, unless complications existed, and Dr. Post was disposed to so regard it himself. In the second place, suppose the operation succeeds, which will be attended with the most inconvenience to the patient? It seemed to him that a pad could be kept over an opening in the loins better than over one in the inguinal region, because the motions of the thigh upon the trunk had a tendency to remove the dressings.

Dr. Briddon thought that, if the opening in Dr. Sands' case was in the small intestine, it must be close to the large intestine, because the contents of the intestinal canal at its upper part would cause excoriation of the external surface.

The President said, that one consideration which would probably curtail the value of the operation in the groin, was the uncertainty that almost necessarily obtained as to the precise point where the alimentary canal is reached. In the lumbar colotomy the precise point could be determined.

Dr. Stimson remarked that, in the *left* groin, the large intestine could be recognized with certainty.

Dr. Sands thought there was no absolute certainty in lumbar colotomy.

Dr. Post said, that in a recent case of lumbar colotomy, it was some time before he was able to make out what portion of the intestine was exposed.

Dr. Lange asked if any difficulty was experienced

in drawing the edges of the peritoneal wound and the skin together.

Dr. Sands said, none whatever; that they were readily united, and no protrusion occurred between the sutures.

Dr. Lange had had no experience in the operation, except in two cases where he performed it for the relief of new-born children with entire absence of the rectum. In both cases there was some difficulty in uniting the peritonæum to the external wound. One of the children survived, and died nine months later of summer complaint, with prolapse of the sigmoid flexure, which gave rise to considerable irrita ion from excoriation and eczema. In the other case the child died from loss of blood and septicæmia.

Dr. Briddon asked if there was any greater liability to prolapse of the intestine after the inguinal than the lumbar operation.

Dr. Sands said he was unable to answer the question. The chief trouble, however, that had been noted had been soiling of the parts by fæces.

Dr. Charles T. Poore then read a paper on

CROSS-LEGGED PROGRESSION [see p. 8].

GUN-SHOT WOUND OF THE LEG OF TWENTY YEARS' STANDING.

Dr. A. C. Post narrated a case as follows: Twenty years ago, a soldier at the second Battle of Bull Run received a gun-shot wound in the right leg, injuring the posterior part of the tibia. He made a partial recovery, but had always had since more or less limp, besides a succession of abscesses, the wound closing and then breaking out again. Several weeks ago there was a large ulcerated surface over the tibia, a little above its middle, and covered with granulations. Last week, Dr. Post found a small opening which allowed a probe to pass its entire length behind the tibia. The patient consented to have done what seemed to be necessary, and accordingly he was anæsthetized, an Esmarch's bandage applied, and a free incision, ten or twelve centimetres long, was made over the surface of the tibia, the periosteum separated from the bone, and a large excavation filled with soft granulation tissue was found behind the tibia. Nearly a double handful of this material was scraped away, leaving the excavation empty and clean. There was no necrosis; but about one-half of the thickness of the tibia had been eroded. No foreign body was discovered. There was considerable oozing of blood from the bone as well as from the soft parts. The wound was plugged firmly, and on the following day there still being some oozing, it was again plugged, and at the next dressing the oozing had ceased entirely, and now the entire surface is in a state of healthy granulation. The tibia was affected at about the junction of the upper and middle thirds. The fibula was not exposed.

[At the Stated Meeting, April 25, 1882, Dr. Post exhibited the leg which had been amputated two weeks. It was removed at the knee-joint. The specimen had been examined by Dr. Satterthwaite, and found to be epithelioma.]

POISONING WITH CARBOLIC ACID.

Dr. Geo. A. Peters related a case, with the following history: A child, three years of age, had suppurative inflammation of the knee-joint with some destruction of tissue, for which he made an incision over the outer side of the joint, large enough to give the finger free admission into the joint under the patella. There was some erosion of the articular surface, and he simply washed out the cavity with a solution of carbolic acid 1 to 40. The spray was used during the operation, and the limb was dressed accurately according to Lister's method. The discharge was free, and the dressing was changed within the first twenty-four hours. Suddenly, the child began to sink, gave the ordinary indications of carbolic acid poisoning, dark-colored urine, etc. The dressings were immediately removed, stimulants were used, and the patient soon began to improve, and finally was out of danger.

Dr. Post referred to the antidotal effect of belladonna in carbolic acid poisoning.

CHRONIC TORTICOLLIS—UNSUCCESSFUL ATTEMPT TO STRETCH THE SPINAL ACCESSORY NERVE.

Dr. Briddon reported a case, with the following history: A man, twenty-six years of age, entered the Presbyterian Hospital on the 24th of February, 1882. He complained of spasm of the muscles of the neck, which had existed for six months, first observed as slight twitchings. The right occiput was incessantly dragged toward the shoulder, and the face to the opposite side, all the muscles of the right side of the neck were in action. The patient was intemperate. There was no history of syphilis.

On the 26th of February Dr. Briddon divided the sterno-mastoid muscle by the open incision, but the torticollis remained unaffected. On the 25th of March he endeavored to expose the spinal accessory nerve for the purpose of stretching it. The incision was made along the centre of the upper half of the sterno-mastoid muscle. Some difficulty was experienced in uncovering the muscle completely, on account of the condition of the tissues which resulted from the operation performed in February. The anterior edge of the muscle was finally exposed and lifted from its bed, but he was unable to find the nerve; nor was he able to do so, after having raised the upper third of the muscle from its bed to a point as high as its insertion into the mastoid process. In doing this a nerve was divided, that upon examination proved to be that branch which passes from the sterno-mastoid to the trapezius. He then divided the muscle transversely, but was not able to find the central end. He then dissected away some connective tissue exposed by the reflection of the muscle, but it contained nothing except lymphatic glands. The dissection laid bare the trachelo-mastoid splenius and anterior border of the trapezius, but revealed no nerve. It was then decided to exsect that portion of the accessory that supplied the trapezius, and about one inch was removed, and the wound was closed. So far no benefit has resulted from the operation.

Dr. Sands said that recently he had had an experience which had taught him something concerning this operation. He was asked to stretch the spinal accessory nerve in a case of clonic spasm, but he finally excised the nerve instead of stretching it. Previous to the operation he endeavored to ascertain, upon the cadaver, the best method of finding the nerve. The directions given by De Morgan are to find the nerve where it emerges at the posterior border of the sterno-mastoid muscle, afterward dissecting through the tissue of the muscle until the upper branch is found. In repeating this operation upon the cadaver, Dr. Sands found a good deal of difficulty in reaching the nerve when it was desired

to divide it without cutting through the greater part of the sterno-mastoid muscle. In six cases he found that the division of the nerve into *two* branches took place very near the anterior border of the muscle, and he thought it would be much easier to reach it by making an incision along the anterior rather than the posterior border. In endeavoring, however, to find the nerve by dissection along the anterior border of the muscle he met with some difficulty. The nerve is there not always exactly in the same locality, and it lies very deeply, being closely related to the internal jugular vein.

Dr. Sands finally adopted as the best plan for finding the nerve, to make an incision along the posterior border of the sterno-mastoid muscle, and find the branch which goes to the trapezius; then to make an incision along the front of the muscle, and use the posterior branch as a tractor by which the tissues overlying the anterior part of the nerve can be made prominent, and thus indicate its situation. Adopting this method in the case referred to, he divided the nerve about half an inch above its division into branches and removed half or three-fourths of an inch. Without this aid afforded by traction, there is a risk of not finding the nerve, and also of doing damage to contiguous parts.

What the result was in his case he did not know. He had met with the report of a remarkable case, in which the spinal accessory nerve was exposed and divided without result; but it having been noticed that pressure upon the sound side of the neck, at the point where the nerve emerged from the muscle, stopped the spasm, the operation was repeated upon that side of the neck with the result of arresting the contractions on the side affected.

Dr. Briddon referred to two cases of clonic torticollis reported by Dr. Southam of the Manchester Royal Infirmary.

In one case, of twenty-seven years' duration, he stretched the nerve through an incision two inches in length along the posterior border of the sterno-mastoid muscle, exposing the nerve as it passes to the trapezius. In the second case he did the same operation, and with the same unsuccessful result.

Dr. Lange referred to a case in which myotomy had been performed without benefit, and in which he stretched the spinal accessory nerve with only slight benefit. Finally he cut through the muscles at the back part of the neck upon the opposite side, as they were evidently hard and contracted during the attack of spasm. That relieved the patient to the extent that he could keep the head quiet, but the protracted effort necessary to do so tired him, and the clonic spasm returned.

RAPID LITHOTRITY.

Dr. J. C. Hutchison presented calculous material removed by rapid lithotrity from the bladder of a man, sixty-nine years of age, who, so far as he could ascertain, first had symptoms of stone two years previous to the operation. There was no history of renal colic. The patient had an enlarged prostate, and had occasionally suffered from retention of urine. The symptoms of stone were not severe. The urine was examined previous to the operation, and found to contain oxalate of lime and uric acid, and the inference was that the calculus was composed of these two constituents. Bigelow's instrument was used, the largest catch being three-fourths of an inch. The stone was crushed without much difficulty and removed through a tube, No. 29, French. Within one hour after the operation the patient got up and walked to the water-closet without inconvenience. The following morning his temperature was 100° F.; he passed his urine without trouble; it was somewhat bloody; his appetite was good, and he felt comfortable. The next morning after that his temperature was normal, the bloody urine had ceased, and the patient was discharged from the hospital cured, within a week. The operation lasted sixty-five minutes, and the amount of material removed was 216 grains. Dr. Hutchison had examined the man's bladder subsequently, and found nothing to indicate the existence of calculous débris or another stone. The lithotrite was introduced but once, and the tube but once. The specimen was interesting, as illustrating the value of rapid lithotrity in old men, and the little disturbance which the operation sometimes gives them.

Dr. Lange exhibited a case containing materials, with special reference to the permanent antiseptic dressing, after which the society proceeded to the transaction of miscellaneous business.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 15, 1882.

Dr. Robert F. Weir, Vice-President, in the Chair.

The Statistical Secretary announced the death of Dr. John W. Corson.

Dr. J. Knight read a paper on

STATIC ELECTRICITY AS A THERAPEUTIC AGENT,

in the use of which he had had experience for over fifty years. The author of the paper regarded the source from which it was obtained as a matter of some importance, and made a brief review of what had been published on that point:

"The earth may therefore be viewed, first, as one large electrical machine, of which the direction of the current is from east to west; and, secondly, as a vast magnet, of which the poles are beneath the surface, and of which the directive force is nearly parallel with its axis, or from north to south. Electricity of the atmosphere (and as termed static electricity), of which the atmosphere abounds, is derived from the thermo-electricity of the atmosphere. Electro-magnetism, represented in the small electrical machines now in use, is simply the reversing of the magnetic poles, eliminating static electricity (Knight).

"Static electricity, from the universality of its action, doubtless plays an all-important part in the sustentation of health, the germination of plants, the production of ozone, rain, snow, hail, and tempest (Prout).

"Static electricity increases in proportion as we ascend from the surface of the earth, and at a certain height becomes uniform and constant. Dry and pure air is one of the most complete non-conductors of static electricity, tending to a maximum quantity, and lessens in gradation to the increase of moisture, the earth being invariably in a minor condition.

"The usual condition of static electricity is in a lower degree during the night, and its minimum at about 3 A.M.; it increases at sunrise, and diminishes about noon, increases again toward sunset, and becomes lessened during the night, being much affected by the winds (Brand).

"Professor Quételet, Astronomer Royal of Belgium, states that atmospheric electricity is in the highest intensity during the month of January, and attains to its minimum in June. The distribution of atmospheric electricity diminishes from the equator to the poles.

"In Norway it rarely thunders; in Iceland once only in two years; in Peru never (Kosmos).

"Professor Glaisher, meteorologist, of London, states that the prevalence of epidemic or pestilential disease has been associated with the absence or deficiency to that of a maximum diffusion of atmospheric electricity; and the mortality has been found to be in the inverse ratio of the amount of electricity with which the air is charged. On the contrary, when the air is charged to a maximum condition throughout the day, the number of deaths decrease. And to this electrical condition or influence I have had ample experience to confirm what has been stated by this high authority, during the visitation of Asiatic cholera in this country."

In the winter of 1834 a glass-cutter applied to him for treatment of his paralyzed right wrist (now known as "dropped hand")—the member being powerless as to extending the hand—produced from exposure to cold water dropping upon his hand and the grindstone upon which he was cutting ornaments upon glass on a cold night in winter.

From a small cylindrical static electrical machine, and a six-ounce Leyden jar having about one-half of the inner and outer surface covered with tinfoil, he applied light shocks to the arm, from the shoulder to the extremity of the phalanges, daily for two weeks, the hand increasing in power all the time, and finally was restored to a normal condition. After this he continued to use static electricity in cases of infantile paralyses and various other neuralgic derangements, in the Baltimore General Dispensary, for six years with most favorable results.

In 1835 he located in New York, and had resorted to the use of static electricity whenever he could, and employed dynamic electricity only when, on account of the condition of the atmosphere, etc., the other form could not be applied. Notwithstanding his preference for static electricity whenever it could be applied, the dynamic electricity was an exceedingly valuable agent.

Static electricity is subject to many forms of application, differing from the dynamic, and, as he believed, more extensively useful as a therapeutic agent; producing two distinct influences upon the animal system, as an *excitant* and decided *sedative*. The dynamic is merely an excitant and not available in diminishing directly morbid nervous energy in muscles as the former, and only indirectly by restoring normal energy by effort, in time. In the operation of static electricity when insulating patients and producing a maximum diffusive quantity of static electricity, and then drawing it off with sharp metallic points connected with the earth, the influence is so great as to induce syncope in delicate persons, as he had frequently witnessed. The influence is only temporary, however, tending to a normal restoration of nervous influence and a reduction of local inflammation.

Electric Shock.—By means of the Leyden jar the most powerful concussion is given, even to the degree of destroying life.

The shock being used as a curative means, can be definitely modified by having a lesser or greater surface of glass coated on both sides with tinfoil, so insulated as not to be connected by two or more inches from the metallic surface on both sides, by which the intensity of the accumulation can be obtained that will give the shock required. By this, decided tetanization of muscles is induced, using, in place of one or both balls of the electrodes, disks of sponge moistened.

These several modifications of static electricity he considered as excitants, or sedative, and subject to diffusion or localization.

The various conditions of the application of static electricity are only preparatory to various modifying effects to be obtained in accordance with the desire and judgment of the practitioner; differing from that of dynamic electricity in its availability to the practitioner as a means of controlling the various morbid conditions of nervous energy, as that of *deficiency* or *excess*, without permanently injuring the normal conditions of tissues or organic functions. Static electricity is a powerful therapeutic agent, requiring not only a profound knowledge of the natural laws regarding it, but an equal knowledge of anatomy and physiology. If applied locally to the muscles, their origin and insertion must be known to the operator, and if made to act through the nerves, then their connection with the nervous centres, their course, anastomoses and termination, also of the laws which regulate the electrical currents in the muscles and nerves, and the relation of these laws to the vital and physical forces. This applies equally to all the devices for generating electricity, and its application as a remedial therapeutic agent.

One of the most common objects of electrical application is to co-operate with vitality. This, indeed, may be considered the central principle in the medical use of electricity. In the nervous system it is illustrated in cases of exhaustion, prostration, enervation and paralysis; in the tissues, in gangrene, erysipelas, in indolent ulcers and deficient nutrition. It will be found, indeed, to enter more or less directly into every case of the application of static electricity.

Electricity constitutes, in the hands of the medical practitioner, a reactive power. According to Matteucci, the nervous system responds to electricity after all other stimulants have ceased to act.

An influence frequently exerted by electricity is that of changing the action of an organ, or the general tone of the system, thereby arresting a diseased condition.

In deficient nutrition, electricity may co-operate in the vital transformation and organization of the nutrient matter, by means of the nervous system or by direct action on the tissues of a part. To produce increased action in the latter case, static or galvanic electricity may be used. This will be done wherever a part needs to be nourished, or the waste of any organ to be replaced. As a general rule, the current should be feeble and the application long-continued and frequent. For this purpose static electricity is much more efficient than dynamic.

In effusions of serum, or lymph, in some forms of hypertrophy, in bony deposits, rheumatic enlargements and every undue organic development, with the exception, perhaps, of some malignant growths, the power of the absorbents needs to be quickened, and this may often be effected by electrical action. In serous effusions accompanied with inflammation, cautious and gentle application of static electricity will be effectual.

CASE.—Col. I——, of Great Barrington, Mass., was most seriously afflicted, having synovitis affecting

nearly every joint in his formation. The cause was exposure to a running stream of cold water for a considerable duration of time, in repairing a mill-dam in the month of April, 1836. The first indication of the invasion was an inability to rotate the neck and then the back and thigh-joints; then the knee and ankle-joints, and finally the arms and wrists, to such a degree as to leave him in an entirely helpless condition. Then followed a chronic diarrhœa, that necessitated the taking of large doses of opium to retain any nutriment. His complexion was sallow, his joints enlarged and painful, but with no appearance of superficial inflammation. This had all intervened from April to November, when treatment by static electricity was commenced and applied daily with light shocks, from the cervical region to the extremities—the patient being placed upon the insulating table. After three months' treatment, varying the mode of application to and from the patient, the diarrhœa ceased and the appetite increased; but an intolerable irascibility ensued, with apparent congestion about the head. Venesection was resorted to, and much relief and comfort afforded the patient. It was then observed that he could again use his hands and had some power to move the elbow and shoulder-joints. After ten days a similar condition of distress ensued, and relief was again afforded by venesection of about sixteen ounces. After this he was able to push a chair before him and thus walk. The joints were much lessened in size and comparatively soft from that of almost cartilaginous hardness. From this time his physical condition gradually improved, and locomotion became more and more tolerable, so that in the following month of May he was able to mount a horse and ride, although his back and neck remained partially fixed.

In the London *Lancet* of June, 1846, a statement appears of Dr. Golding Bird's experience in the use of static electricity in Guy's Hospital, London, which agreed most closely with his own. Dr. Bird, from his large experience, classified the following forms of paralysis that are relieved by the judicious application of static electricity:

1. Partial paralysis from organic congestion, or effusion, which has been removed. 2. Paralysis of the portio dura, of the seventh pair, from exposure to cold. 3. Paralysis of a limb from the same cause. 4. Paralysis of one side of the body or a single limb, from exhaustion—as from lactation and flooding. 5. Paraplegia from rheumatism, paraplegia from enervation.

He found the use of electricity most successful in recent cases, and contends against its use in many of the established organic lesions; stating that he has known fatal apoplexy to follow its application in cases of ramolissement of the brain, or where indurated arteries existed. Dr. Knight here stated that venesection is essential in the treatment of these cases with static electricity, and dangerous if omitted.

In regard to the efficiency of static electricity, Dr. Golding Bird expresses his favorable opinion of its use in the treatment of nervous diseases, of which a synopsis was given.

Dropped hands are often the result of long continued position of the hands in a state of tension, as occurs in some occupations when closely applied to labor—shoemakers, clerks, and persons engaged on fine needle-work, or any similar employment requiring the fingers to be fixed and long retained in a state of tension. Of this class of patients, nearly every one is perfectly curable with static electricity, and often after dynamic electricity has failed.

In the treatment of this variety of partial paralysis of the forearm and hand, we but seldom insulate the patient, and simply pass light shocks from the elbow to the extremities of the fingers, having an elastic spring support applied, to keep the hand extended by such support. From this treatment of patients under fifty years of age laboring under this ailment, we know of no failures to improve the condition of the arm and hand, although a great number presented themselves for treatment, every year, at the Hospital for the Relief of the Ruptured and Crippled. Ordinary splints to keep the hand extended serve a tolerable purpose, and should be made available where elastic support cannot be obtained.

In the use of static electricity as a curative means, great care in its application was necessary. He had seen patients irrecoverably injured by injudicious treatment with both static and dynamic electricity. Matteucci had pointed out the entire exhaustion of nervous power, similar to paralysis, resulting from an excessive use of electricity. If the improvement ceases under the use of electricity, Dr. Knight recommended the discontinuance of the agent for a week or two. The progress in treatment by electricity is by this interim of rest rendered again susceptible to improvement, and more especially after a strengthening regimen, with tonics and friction, carefully guarding the patient from exposure to cold.

Dr. C. L. Dana had used static electricity considerably during the last six months, and had been satisfied with the results obtained. Recently he had been interested concerning one point, namely, as to how deep the electric current was diffused. He had had two cases in which the functions of the liver seemed to be stimulated by the local application of sparks. It was a question whether the action was direct or reflex. A study of the subject led to the view that when the patient is isolated and charged he is in a kind of electrical bath, the electricity being entirely superficial. Dr. Dana then recited several experiments he had performed with the view to obtaining information on this point. From what he had been able to learn by these experiments, as well as by study of books and questioning one or two physicists, he concluded that static electricity did not penetrate the body to any great extent. When strong sparks are drawn there is some local penetration. That there were good effects produced in a reflex manner there could be no doubt. He also knew that tonic effects were produced sometimes. It remained to be proved, however, that benefit is obtained in a larger percentage of cases requiring tonics by the use of static than by the use of dynamic electricity.

Dr. W. J. Morton reviewed the history of static electricity, and claimed the credit of having revived its medical use in this country, a fact which the author of the paper had not mentioned. He believed that it should be used in large quantities, rather than in the small quantities recommended by Dr. Knight. He thought there was no efficacy whatever in the shock from the Leyden jar. He believed that, in order to obtain the best results, the electricity should be applied as near as possible to the diseased tissue; and that it should not be used as a general agent, as is exercise, bathing, hygienic measures, etc. The classes of cases in which he had found static electricity especially serviceable were: (1) cases of spinal irritation so-called; (2) soreness after subacute and chronic rheumatism and gout;

and (3) when he wished to exert the muscles, as in cases of infantile paralysis.

Dr. A. D. Rockwell thought the interesting question was not so much as to the absolute value of static electricity as to its value when compared with other forms of electricty now in general use. To Dr. Morton belonged the credit of having revived the subject of the use of static electricity, and with him he agreed that it had a tonic restorative power of high order; but that static and dynamic electricity were equal in therapeutic value, he did not endorse, and he regarded it as unfortunate to have the idea get abroad that the static was superior to the dynamic, when it was not. One benefit which he had derived from the use of static electricity had come from its supplementary power; that is, when dynamic electricity had ceased to produce effects, or reduced effects, the static would, in many cases act satisfactorily, With reference to the depth to which electricity penetrates the body, he thought that the inner portions of the body were affected considerably.

Dr. Knight said, in closing the discussion, that certainly Dr. Morton was entitled to the credit of having revived the use of static electricity in this country, and he was unable to understand why such an omission had been made in his paper.

Dr. F. D. Lente then read a paper on

A HITHERTO UNDESCRIBED LESION OF THE KNEE-JOINT.

Without naming the conditions, he gave its clinical picture by the recitation of several cases. It results from a variety of injuries, apparently of a trivial character, perhaps the most common was that which twisted the joint slightly and gave the patient almost momentary inconvenience, followed by slight pain and stiffness, more pain on the following day, increased by walking; improved under treatment with splints and relapsed as soon as they are removed; slight swelling with thickening of the tissues, perhaps slight effusion into the joint, no heat, etc. In this condition there is usually less pain when the limb is straight, whereas when the joint is diseased the flexed position is most comfortable. There is a point of tenderness on the inner aspect of the knee. The treatment which he had adopted successfully had been a fixed dressing—silicate of soda splint—worn uninterruptedly until the knee got well. For the pain, blisters might be required, and these could be applied through fenestra. The stiffness which remained after removal of the splint could be readily overcome by passive motion. Forcible rupture of the fibrous anchylosis might be necessary in exceptional cases, where the patient lacked the fortitude necessary to endure the passive movements.

Dr. Weir referred to cases in which slight injury of the knee-joint had been followed by serious lesions, and the most satisfactory results had been obtained by such treatment as secured absolute rest. He had been rather inclined to look upon some of these cases as ones in which there was inflammation of a semilunar cartilage, and in certain cases the difficulty might go on to the development of fungoid disease. The severer forms, however, had not been considered in the paper, but only the milder forms and the plan of treatment was eminently practical.

Dr. L. H. Sayre referred to the great liability of slight injuries of the knee-joint, also other joints, being overlooked when really all such injuries were of a serious character, because they might be the starting-point of what would destroy the usefulness of the limb. Most serious joint disease had very frequently commenced in just the way Dr. Lente had described.

Dr. A. B. Judson supposed that it was impossible to make an absolute diagnosis of the exact lesion in these cases, because of the inability to look in, and therefore we were at liberty perhaps to indulge in surmise concerning the portion of the joint primarily affected. It had occurred to him that possibly the explanation could be reached by the supposition that some tissue of the joint, cartilage, ligament, or bone might be in a morbid condition, which rendered it liable to suffer discomfort which otherwise would pass without notice. He regarded them as cases of disease of some tissue entering into the formation of the joint rather than cases of accident.

Dr. Gibney asked Dr. Lente what lesion he had diagnosticated.

Dr. Lente said that he had not made a diagnosis. But from the fact that the painful point in all the cases had been within half an inch of the same anatomical position he had thought it might be a condition due to straining of the semilunar cartilage on the inner side of the joint.

Dr. Gibney said it was somewhat difficult to say whether any of these cases were neuroses or not. But the lameness appearing so soon after the injury made the condition appear as though it might be ligamentous arthritis, and put the patients into that class which get into the hands of bone-setters and yield such brilliant results. There was one interesting point in connection with the treatment and it was that joints can be kept fixed for a long time without danger of anchylosis.

Dr. Lente thought that pre-existing disease could be excluded in his cases, because all the patients were apparently in the most perfect health when the injury was received. In all the cases which he had seen, with a single exception; there was no evidence of the existence of any nervous affection or hysteria.

The Academy then adjourned, to meet on the first Thursday in October.

NEW HAMPSHIRE MEDICAL SOCIETY.

Ninety-Second Annual Meeting, held at Concord, June 20 and 21, 1882.

(Reported for The Medical Record.)

The Association met in Union Hall at 11 o'clock A.M., the President, Dr. Hadley B. Fowler, in the Chair.

After the ordinary routine of business incident to the opening, the report of the meeting of the Councillors was read by the Secretary and approved by the Society, and upon their recommendation eighteen new members were elected, who appeared, and were admitted into full fellowship after signing the Constitution and by-laws of the Society. Several other applications for membership were favorably acted upon by the Council, but a rule of the Society requires the applicant to be present to sign the Constitution as a proof of his intention of becoming a *bona fide* member; therefore, all such applications were laid on the table until such time as the friend or voucher for the applicant should call it up.

The roster of the Society showed that over one hundred and thirty members were present, which is a large number for a society of only two hundred active members in a State like New Hampshire, that is sparsely settled, and has but a few moderate-sized business centres.

It is one of the by-laws of the Society that the President shall deliver an address at noon of the first day of the meeting. Consequently, at that hour the Vice-President, Dr. Crosby, of Concord, assumed the chair, and PRESIDENT FOWLER read an excellent paper, that was listened to by the Association with the closest attention.

He referred in fitting terms to the members deceased during the past year; congratulated the Society upon its general prosperity, and then devoted a little time to the ethical relations existing between the profession and the pharmacist.

The Doctor was very severe upon physicians who endorsed or recommended any proprietary medicines. In regard to the temperance laws, he recommended that every one be held responsible for his own acts, and that drunkenness be declared a crime punishable with a fine for first offence, and by five years' imprisonment for sixth offence. The address was full of wise words, kindly spoken, witty and instructive, and will be published.

DR. C. F. LESLIE, of Sunapee, read a report on Practical Medicine, devoting a considerable portion of the paper to typhoid fever, that seems to be particularly prevalent in his locality. The town is situated on a lake of the same name, the principal village being at the outlet. This body of water is about ten miles long, with varying width, of from one-fourth to one mile; is about twelve hundred feet above the level of the sea, and is very clear and cold; with a *minimum* of alluvial land about its shores, or of deposit in the bottom. The doctor reported that he had treated cases of typhoid fever, occurring in every month of the year, and always had the most cases when the water in the lake was the highest. From this one might infer that the lake water had some source of contamination that was directly responsible for the frequency of the fever; but, as the water of the lake is not used for domestic purposes, it would seem that it was a coincidence rather than a cause.

PROF. FIELD, of Dartmouth Medical College, read an essay on "The Balsamic," that was well written and exhaustive in its character; and a mere abstract of the paper would fail to do him justice.

DR. E. F. MCQUESTION, of Nashua, read a report on surgery, giving a review of the legal case of Holt vs. McQuestion, tried in Hillsborough County, in 1881, for alleged malpractice (in which the verdict was given for the defendant), and several other surgical cases where the ankle-joint was injured. He recommended that the society prepare a new law which will oblige those parties bringing suits for malpractice to give bonds to indemnify the defendants if their charges are not sustained.

DR. G. L. MASON, of Laconia, delivered an oration on the "Now and Then" of the medical and surgical methods of the orthodox practitioners. He spoke of some of the remarkable cures effected by the heroic treatment of old, and asked the question: Would they get well now if bled and blistered and dosed with tartarized antimony as they were a half century since?

DR. SMITH, of Hanover, exhibited a "horseshoe" kidney, and read an essay upon the subject.

DR. I. A. WATSON, Secretary of the State Board of Health, read a paper on "State Medicine," recommending to the medical profession the educating of the people upon sanitary and hygienic matters as the only effectual method of the prevention of diseases that are produced by bad sanitary conditions. He pointed out many of the dangers of improper ventilation of dwelling-houses, school-rooms, churches, public halls, etc.; also the serious results that follow water contamination, and the great danger of pollution of wells and springs from the filthy conditions that surround many houses. Many instances and illustrations were given, showing that the poison of typhoid fever and some other diseases might be conveyed a long distance in water currents, even under ground, and then produce disease in some other localities. He asserted, with proof, that the popular idea that ice was always pure because the process of freezing eliminated its organic impurities, was a false theory, and that ice from any source but that of pure water was dangerous to health. He believed that the public entertained false ideas concerning contagious diseases; that scarlet fever and diphtheria should always be as promptly and efficiently isolated as small-pox, since they were infinitely more fatal diseases. The paper appealed strongly to the profession to endeavor to correct many erroneous ideas and to leave no efforts undone to prevent disease and to secure the greatest possible good for the people. He urged the profession to become co-workers with the State Board of Health to secure such reforms.

DR. M. T. STONE, of Troy, read a dissertation upon tobacco, and DR. H. M. FELT, of Hillsboro, a paper upon "Emetic Medication." All the above papers were referred to the Committee on Publications.

The anniversary dinner was served at the Phenix Hotel and *post prandial* exercises were conducted by the Anniversary Chairman, Dr. Chas. A. Tufts, of Dover, who in well-chosen words introduced President Fowler to respond for the New Hampshire Medical Society. His Honor G. A. Cummings welcomed the visiting physicians to the city of Concord.

REV. MR. PARKHURST responded for the clergy and gave a fine description of the doctor's influence upon the community in which he lives.

HON. J. W. PATTERSON responded to the cause of education. He pleaded for the assimilation of mental food to insure mental growth.

DR. GAMWELL responded for the Massachusetts Medical Society.

During the evening session the Committee on Necrology reported the deaths of Dr. E. K. Webster, of Pittsfield; Dr. Harrison Eaton, of Merrimack; Dr. John A. Dana, of Ashland; and Dr. A. B. Hoyt, of Grafton. All the decedents had been honored members of the Society for a great many years, and appropriate notices were read and referred to the Committee on Publications.

On Wednesday the Society convened at eight o'clock in the morning, when reports of committees and delegates were in order, and at nine o'clock the following officers were elected:

President, Dr. A. H. Crosby, of Concord; *Vice-President*, Dr. J. W. Parsons, of Portsmouth; *Treasurer*, Dr. D. S. Adams, of Manchester; *Secretary*, Dr. G. P. Conn, of Concord; *Anniversary Chairman*, Dr. A. P. Richardson, of Walpole; *Executive Committee*, Drs. J. W. Parsons, of Portsmouth; P. A. Stackpole, of Dover; and M. W. Russell, of Concord, with a Council consisting of twenty members and a board of ten Censors. Also delegates to Dartmouth Medical College and the various State societies and the American Medical Association.

The Committee on Patients reported upon the cases presented to their notice, and considerable time was spent in miscellaneous business, when, at 12.30 P.M., the Society adjourned, to meet again in Concord the third Tuesday in June, 1883.

Correspondence.

MEDICAL IMPRESSIONS OF CHINA.

To the Editor of The Medical Record.

Sir: On my return from Canton, ninety miles distant from Hong Kong, it occurred to me that a brief sketch of a few features of this most characteristic of Chinese towns, might be of interest to the readers of The Medical Record.

Canton, the provincial capital, with one million inhabitants, lies on the north bank of the Pearl River, in latitude 23° 7′ 10″ N., and 113° 14′ 30″ E. longitude, nearly parallel with Havana and Calcutta; its climate, however, is colder than that of either of these cities. The houses are, with few exceptions, of only one story. The streets are very narrow, not exceeding six feet in width. The houses of the better class are built of substantial brick; those of the poor, with sun-dried brick. The roofs are massive, being covered with closely overlapping tiles. From the condition of the great bulk of the houses of the lower classes—these houses having earth floors, and a damp subsoil—rheumatism is a common complaint. The cases of rheumatism are almost entirely muscular or syphilitic; the acute variety being rarely met with. There is a complete disregard of sanitary laws. No closed underground sewers or drains exist, save a rudely-constructed covered gutter in the centre of the street, which carries off the superfluous rain and the slops of the houses lining the wayside. These drains are covered with stone slabs, placed so far apart that one can see the water beneath them; and the air, saturated with impurities of human excreta and other decomposed substances which emanate from the drains and privies, defies the tolerance of even well-blunted olfactories. Even my Chinese guide was forced, every now and then, to compress his nostrils as we made our way through the city; and yet this air is inhaled by the native apparently with utter impunity, for, with the exception of ague, which is quite prevalent, the diseases which we should expect to find very general are met with only exceptionally. The latrines are very numerous, and nothing is used to interfere with the results of decomposition. Their contents are allowed to accumulate for days, until they are filled, and they are disposed of to the farmer, and carried through the streets to the jetties in uncovered buckets, generally during the day. Filthy creeks, containing decomposed refuse, ramify into different parts of the city, discharging their nauseous odors at the doors, and, in many instances, under the floors of the houses. The river water is greatly used, and that used for culinary purposes by the floating population, or those who live in sampans or boats, along the jetties, is extremely filthy, and must be contaminated with human excreta and other impurities. Here, then, are the causes which are supposed to produce typhoid fever, in full operation, but this disease is rarely met with in Canton. However, the evidence favoring the view that the poison of typhoid fever is communicated through contaminated water is not weakened by the absence of this disease in this and other Chinese towns, because the water drunk is, perhaps, always first boiled and is generally used in the form of tea: the process of boiling would necessarily destroy the organisms which are supposed to give rise to this disease. The privies of the natives are mostly out of doors; those of the foreign population, although in the house, are of the portable kind, and are visited daily by a scavenger, who carries off the contents. The Chinese collect and preserve with the greatest care every particle of every kind of manure, besides rags and paper, etc., and turn them to practical use. Human manure is of high value, and is, therefore, collected with great assiduity for agricultural purposes; large numbers of people in this way obtain a living. The healthiness of the foreign population of Canton is certainly in a great measure owing to the absence of water-closets in the dwelling-houses, which at home are a fruitful source of disease. Sulphuretted and carburetted hydrogen gases are evidently not so injurious to health when given off in the open air as when escaping from sewers. Canton, like the whole country, is a city of bad smells, and yet the people do not seem to suffer from them, but, on the contrary, rather like them. The removal of excreta, and the disposal of sewer water is the sanitary problem of the day at home and abroad. Our sewers allow the transference of gases and organic molecules from house to house and from place to place. Occasionally, by bursting, leakage, or absorption, the ground is contaminated, and the water supply is in danger of being contaminated and poisoned; and all these dangers are greater from being concealed. In China, there is at least freedom from one of these dangers. *It would certainly seem advisable that our water-closets should be in a projection from the building, with a tube passing to the outer air.* There is something instructive to us in the effects of the absence of sanitary law in this Chinese city. There is no typhus, rarely typhoid, and none of the other diseases, diphtheria, etc. (considered the inevitable consequence of defective sanitation), although Canton, as well as every other Chinese town, is full of typical typhus dens. Fortunately, however, filth, overcrowding, and poor food are not the only factors necessary for a typhus epidemic, or else the lot of the foreign residents in China would be a sad one indeed.

I cannot close without paying a passing tribute to the zeal and indefatigable devotion to medical science which I witnessed in the American Medical Missionary, Dr. J. G. Kerr, in Canton. This gentleman has practised his profession in China twenty-nine years, and is well known in America as one who has performed lithotomy perhaps oftener than any living surgeon; but I am sure that, owing to the great modesty of the man, only a small part of the good work he is doing is known to his countrymen. He is a well-informed surgeon, and the amount and quality of the work performed by him at his hospital, under so many disadvantages, is remarkable. There are accommodations for one hundred and fifty patients in his hospital, and the attendance of outpatients is very large. In addition to the arduous duties at the hospital, the doctor devotes much labor to translating into Chinese such English works as he believes will be useful to the people among whom he is passing a life of such self-sacrifice. A more useful and sincere medical man does not live in the East.

Joseph A. Andrews, M.D.

Hong Kong, May 9, 1882.

A Garibaldi Memorial Hospital.—Efforts are making to secure money for the erection of a Garibaldi Memorial Hospital, at Clifton, S. I., where he used to live.

PRELIMINARY NOTES OF AUTOPSY HELD UPON THE BODY OF CHARLES J. GUITEAU.

To the Editor of The Medical Record.

Sir: As requested by you, we enclose preliminary notes of the autopsy held upon the body of Guiteau. The examination was made under the direction of Dr. Lamb, U.S.A., to whose courtesy we are indebted. Each physician present was left at liberty to make his own notes and observations. Those enclosed are compiled equally from notes independently taken by us. We were greatly assisted also by Dr. Chas. K. Mills, of Philadelphia.

Dr. Lamb will publish, later, a full report which this does not forestall, but to which it is, as stated, simply preliminary.

Wm. J. Morton, M.D.
Chas. L. Dana, M.D.

New York City, July 5, 1882.

The post-mortem was held about three-quarters of an hour after death.

GENERAL APPEARANCE OF BODY.

The body was still warm; the limbs flaccid. There was no emaciation. The skin had a marked yellowish tinge. There was a slight but wide-spread ecchymosis upon the left side of the face. When the body was first taken down the eyeballs protruded and the lids were open.

A brownish red mark, made by the rope, extended three-fourths of the way around the neck, the knot having evidently slipped from the left side to the back. The mark went just above the thyroid cartilage.

The penis showed that there had been an erection and emission. There was a tight prepuce, with slight adhesions and abundant smegma. There was no mark of a venereal sore.

The eyes.—The pupils were slightly and equally dilated, the vitreous cloudy, and fundus indistinguishable.

Abdominal cavity.—Section through the median line showed considerable deposit of fat. The liver was congested, but otherwise normal. The gall-bladder contained a little bile. The spleen was enlarged. Its weight was fifteen ounces. Its tissue appeared normal. The other abdominal viscera were normal. The bladder contained about five ounces of urine.

Thoracic organs.—In opening the thorax a slight venous effusion was found in the right pectoralis major muscle.

The heart was firm. A soft clot was being formed in the right ventricle. The left ventricle was empty. The heart ceased action in systole. Weight, 10½ ounces. A spot of old inflammation existed on left ventricle near the apex. There was a slight atheroma at the beginning of the aorta. There were a few pleuretic adhesions on each side. The pleural cavities were empty. The lungs were slightly congested. A few small, gray bodies resembling miliary tubercles were found in middle part of the left lung near the outer external surface. Otherwise everything was essentially normal.

The neck.—There was externally a mark, as has been described. Both the sterno-cleido-mastoid muscles were ruptured; also the thyro-hyoid membrane. The hyoid bone was not broken, nor the laryngeal cartilages. There was no fracture or dislocation of the vertebræ.

HEAD, SKULL AND BRAIN.

The appearance of the face and eyes has been described. There was a scar on the scalp an inch long. It was situated above and behind the left temple at about two-thirds the height and an inch in front of the auriculo-bregmatic line. It extended through the scalp, but there was no corresponding mark of any kind upon the skull.

The skull.—The most noticeable asymmetry was a slight flattening of the upper and anterior part of the right parietal bone. The flattening ended sharply at the coronal suture. It included a space about half the size of the palm of the hand. Other points of asymmetry were not sufficiently noticeable to be studied with the means at our command.

The cranial sutures were distinct. There was no visible trace of a frontal suture, the two halves of the frontal bone being thoroughly welded. On the inner surface of the skull the bony prominences were well marked; also the Pacchionian depressions. No abnormalities were discovered. There was a slight prominence corresponding to the flattening of the parietal bone before mentioned.

The thickness of the skull was not measured owing to lack of facilities. An attempt was made to measure its cubic contents but it failed for the same reason. As regards thickness there was no striking abnormality at least.

The relative size of the fossæ could not be accurately determined at the time of autopsy.

Brain membranes.—The dura mater was quite strongly adherent in places to the inner surface of the skull. Near the trunks of the middle meningeal arteries upon each side the membrane was thickened and strongly adherent to the bone, though it could be stripped clean. It was also adherent near the longitudinal sinus in front. There was at these points, probably, a slight chronic pachymeningitis externa. There was no exudation upon the inner surface of the dura anywhere. The cerebral sinuses contained but little blood. There was rather more than the average amount of Pacchionian granulations distributed along the middle part of the upper surface.

The arachnoid.—There were very well-marked milky opacities of the arachnoid extending over the upper convex surface. These opacities were over the fissures only. In some parts they had a somewhat yellowish look.

The subarachnoid space contained no abnormal amount of fluid.

The *pia mater* presented no abnormal appearance. It came off easily from the brain.

The *blood-vessels* of the membranes and brain were not full, and the general appearance of the brain was anæmic.

There was no special examination of the larger vessels.

THE BRAIN.

The *weight* was forty-nine and a half ounces (measured on a grocer's scales).

Its *consistence* appeared to be normal.

Its *specific gravity* could not be obtained owing to lack of facilities.

The *measurement* of its *chords and arcs* could not be obtained for the same reason.

As regards *contour and shape* exact studies could not be made. There was no apparent asymmetry of the two hemispheres.

The *comparative weights* of the cerebra and the other parts could not be obtained.

The *cerebellum* was well covered. The occipital lobes were not noticeably blunt or sharp.

The frontal lobes were peculiarly shaped. Looking at them from in front and above, they presented two protruding points from which the surface sloped away in a concave curve. This pointed apex of the lobes with the concavity of the orbital and beginning of the frontal surface was carefully noted by all of us at the first exposure and removal of the brain.

THE LOBES AND CONVOLUTIONS.

Frontal lobes.—Their peculiar shape has been referred to. As regards size they appeared to be well developed.

THE FRONTAL LOBES—LEFT SIDE.

The *first frontal fissure* was very long. It was broken by a single bridge near the junction of the anterior and middle-thirds. The *secondary fissure* was very marked, so much so that it seemed almost to form an independent primary fissure. The *second frontal fissure* was well defined, but interrupted by four small concealed connecting convolutions. It communicated with the first by a cross fissure. It was not confluent with the præcentral fissure.

The *præcentral fissure* was well defined and not confluent. The convex surface of this lobe, as a whole, was marked with an unusual number of cross and other secondary fissures. It was not of a confluent type, but it showed a marked tendency to the four-convolution type.

The *orbital surface* showed a radiate orbital fissure starting from a single central depression or fissure. There were five radiate fissures from this centre. The olfactory fissure showed nothing peculiar.

THE FRONTAL LOBES—RIGHT SIDE.

The *first frontal fissure* was well defined, non-confluent, except that at its posterior extremity it communicated with a deep cross fissure. The secondary fissure was a typical one. The *second frontal fissure* was well defined and non-confluent.

Præcentral fissure.—(No notes.)

The orbital surface was well fissured. The *orbital fissure* branched off from a small isolated central convolution in seven different rays.

The olfactory fissure was normal.

The right frontal lobe was not of a confluent type nor four-fissured, but had an usual development of secondary fissures, like the left lobe.

THE PARIETAL LOBES—LEFT SIDE.

Fissure of Sylvius.—The distance of its lower end from the apex of the frontal was not measured; nor the angle it formed with a horizontal plane. In both these respects it *appeared* to be normal. There was a partial confluence with the first temporal and also with the fissure of Rolando. From the surface it appeared as if the latter fissure passed directly into the Sylvian. On parting the convolutions, however, a connecting convolution was seen. The fissure seemed to be of average length.

The *anterior branch* was well defined and non-confluent.

The *fissure of Rolando* was well defined and not confluent. The præ- and post-central convolutions as well as the paracentral lobule were large and well developed.

The *retro-central fissure* was well-defined and separated from the interparietal by a small concealed connecting convolution.

THE RIGHT SIDE.

The *fissure of Sylvius.*—There was no confluence, apparent or real, of this fissure.

The *anterior branch.*—(No notes.)

The *fissure of Rolando* was well defined and non-confluent. It extended slightly into the longitudinal fissure, fissuring the paracentral lobule. The central convolutions, as they lay under the depressed parietal bone, were examined with special care. The præcentral convolution was well developed throughout its whole length. The post-central convolution was well developed up to its upper fourth. Here it became narrow and shrunken.

The *paracentral lobule* was quite small. On the left side, *per contra*, this lobule was well developed, while the fissure of Rolando was separated from the longitudinal fissure by a broad convolution. (There was a deficient innervation of the left side of the face.)

The *retro-central fissure* was well defined and confluent with the interparietal.

THE LEFT SIDE.

Island of Reil was well covered. Seven straight fissures and eight convolutions were present.

The *interparietal fissure* began at retro-central and ran a well-defined course, ending in the transverse occipital, from which it was separated, however, by a small convolution. It had no complete confluences.

THE RIGHT SIDE.

The *island of Reil* was well covered and had five straight fissures and six convolutions.

The *intraparietal fissure* began in and was confluent with the retro-central. It was well defined. No abnormal confluences noted.

TEMPERO-SPHENOIDAL LOBES—LEFT SIDE.

The *first temporal fissure* was well defined for depth, but was not so long as usual—not running up to the angular gyrus. It was slightly confluent with the fissure of Sylvius.

The *second temporal fissure* was not especially well defined.

On the basal surface the *inferior temporal fissure* was well defined and not confluent.

The *collateral fissure* was well defined and long, extending to the anterior end of the temporal lobe.

The *fusiform lobule* was smaller on this, the left side, than on the right.

ON THE RIGHT SIDE.

The *first temporal fissure* was well defined and of normal length, with no confluences.

The *second temporal fissure.*—(No notes.)

On the basal surface the *inferior temporal fissure* was normal. It was incompletely confluent with the *collateral fissure*, which was well defined but shorter than that on the left side.

THE OCCIPITAL LOBES.

The *primary fissures* were present in these lobes on both sides and no especial peculiarities were noted.

The *anterior occipital*, or Wernicke's fissure, was present on each side, was well defined and non-confluent.

The *right transverse fissure* was well defined, beginning on the mesal surface and passing out with two small interrupting convolutions.

The *left transverse fissure* was well defined; nothing further noted.

Thus, of the three fissures which combine in apes

to form the ape-fissure, viz., the second temporal, the anterior occipital (Wernicke's), and the transverse occipital, two were only normally defined; the remaining (the temporal) was not strongly marked.

MESAL SURFACE—LEFT SIDE.

The *calloso-marginal fissure* ran its usual course to form the anterior boundary of the præcuneus. It was broken in the last part at the præcuneus by a convolution.

Above this fissure was a secondary fissure, running parallel to it and ending about opposite the first third of the corpus callosum.

ON THE RIGHT SIDE.

The *calloso-marginal fissure* was continued on through the præcuneus to the parieto-occipital fissure, from which it was separated by a small convolution.

The *secondary fissure* upon this side was still more developed than on the left, and ran back to the anterior boundary of the paracentral lobule.

On the whole it would appear (1) that the brain was marked by an unusual number of cross and secondary fissures, especially in the frontal lobes; (2) that it was not of the confluent fissure type; (3) that the convolutions on the two hemispheres were quite asymmetrical.

THE INTERIOR OF THE BRAIN.

The white substance was somewhat whiter than usual, and of normal consistency.

The gray cortex was measured and seemed to be somewhat thinner than usual. Eight or nine measurements in different parts gave a thickness varying between $\frac{1}{8}$ $\frac{1}{9}$ $\frac{1}{12}$ $\frac{1}{16}$ of an inch.

The *ventricles* were dry, the ependyma normal, the choroid plexus showed nothing noticeable. No spots of hemorrhage or softening were found, and no tumor was present.

THE CEREBELLUM.

Nothing peculiar was noted regarding this portion of the brain.

The brain was finally cut into various pieces.

Portions were distributed for microscopic examination.

Medical Items and News.

DEATH OF PROFESSOR JAMES SPENCE.—Professor Spence, F.R.S., F.R.C., etc., of Edinburgh, died in that city on June 6, 1882, in the 70th year of his age. He was Professor of Surgery in the University of Edinburgh, Surgeon to the Royal Infirmary, and late President of the Edinburgh Royal College of Surgeons. He became a Licentiate of the Royal College of Surgeons at Edinburgh in 1832, and a Fellow in 1849. He was at different times Lecturer on Surgery at the Surgical Hall, on Clinical Surgery at the Edinburgh Royal Infirmary, Surgeon to the Royal Dispensary and Lock Hospital, Consulting Surgeon to the Royal Hospital for Sick Children, and a member of the Harveian and other societies. He was appointed Professor of Surgery in the University of Edinburgh in 1864, and in 1865 Surgeon in Ordinary to the Queen in Scotland in place of the late Dr. David Maclagan. He contributed several papers on professional subjects to the Edinburgh *Medical Journal*, and published, in 1871, "Lectures on Surgery," in two volumes.

FORCIBLE ALIMENTATION IN PHTHISIS.—Wide circulation and some very injudicious comment is being given to Debove's method of feeding phthisical patients with a tube except in very rare cases. It is impossible that such a measure should have any utility outside of well-drilled and submissive hospital patients. Few foods are more nauseating than a tube thrust down the throat. The nose is perhaps saved but the vomiting is doubly excited in the pharynx and in the stomach.

THERAPEUTICAL NOTES.—Iridin is a possible preventive of the formation of gall-stones.

Tincture of tayuya, a Brazilian plant, is reported from Italy as an efficient anti-syphilitic. The dose is from six to sixty drops.

Wood betony (Betonica), a revived remedy, is the latest addition to the anti-alcoholic drugs.

The sugared *milk of papaine* injected into parasitic tumors has been found to resolve them.

Arsenic will often cure cases of pernicious anæmia where iron fails.

Hydrarg. bichlor. in small continuous doses causes an increase of weight in healthy persons.

Fuchsine (gr. ss. in pill), twice daily, acts wonderfully well in albuminuria, especially where there are contracted kidneys.

Hypodermic injection of cold water over the epigastrium has been found curative of phthisical and of nervous vomiting.

In asthma Dr. Murrell found drachm doses of *resorcin* in milk curative, but it is apt to cause symptoms similar to carbolic acid poisoning.

M. Vidal in *non-puerperal peritonitis*, and in broncho-pneumonia of infants, has found excellent results from flannel compresses, saturated with turpentine, and covered with oiled silk. In an hour vesication occurs, with rise of pulse and increase of strength.—*Australian Medical Journal.*

EFFECT ON WOMEN OF IMPERFECT SEXUAL HYGIENE.—Dr. Chas. Fayette Taylor *(American Jour. of Obstet. and Diseases of Women and Children)* argues that many of the invalids among the unmarried women, especially those of the highest and most refined class, have been ruined in health, and often in mind, by *disuse* of the sexual organs. He states that in many instances the subjects are entirely ignorant of the cause and even of the nature of the erotic sensations—all such ideas and influences having been, by education and training, methodically repressed from infancy. Many form the habit of masturbation, and are thus undermined in health.

CENTRAL PULMONARY ABSCESS MISTAKEN FOR A CASE OF EMPYEMA.—The *Lancet* for April 15, 1882, contains a case of pulmonary abscess reported by Dr. Henry Payne, M.R.C.S., which the author regards, in accordance with modern authorities (Ziemssen and Reynolds) as one of those rare instances where abscess is a sequel to chronic pneumonia. The patient, a male, twenty-three years of age, was admitted into the Ashton-under-Lyne Infirmary exhibiting marked signs of pleurisy with effusion. Ordinary routine treatment was instituted and kept up for a month, when an examination revealed great emaciation; bulging of the left chest wall with an increase in measurement by an inch, as compared with the right; complete dulness on percussion, both front and rear; absence of vocal fremitus and vocal resonance, and also of the breath sounds. Over the right lung the breathing was exaggerated. There was a double aortic murmur but no apex

beat. Slight cough and elevated temperature toward evening. The hypodermic needle detected pus. An operation, to relieve an empyema, was advised, and an opening, two inches long, was made under antiseptic precautions, into what was supposed to be the pleural sac. Severe hemorrhage, with about fifteen ounces of pus, followed. Immediate relief was afforded, and for some five or six days the patient did well, when his temperature suddenly reached 103.4 F., and he died. An autopsy disclosed the following facts: Absence of any pleural sac whatever on the left side; an opening externally leading directly into an irregular cavity in the centre of the left lung, which was in the gray stage of hepatization. Right lung healthy.

The author cites Trousseau, who, during the first twenty-five years of his hospital experience, never found a single instance of a purely inflammatory (*i. e.* non-metastatic non-tuberculous) abscess following chronic pneumonia. Laennec, also quoted, found only five in several hundred autopsies.

CHRONIC URTICARIA WITH INTENSE ITCHING CURED BY JABORANDI.—Dr. C. L. Dana relates the history of a case (*Journal of Nervous and Mental Diseases*) in which an obstinate urticaria was permanently relieved by small doses of jaborandi.

The patient, a shop-girl, aged twenty-one, had suffered from chronic urticaria, with the most troublesome pruritus, for two winters. She was a healthy girl except for occasional attacks of malaria. Suffered also from constipation.

She would have occasional attacks of intense congestion of the face, often obliging her to lie down. At night the symptoms of urticaria were the worst. The legs and arms became very red, and wheals appeared. Patient suffered intensely from the itching.

The first winter she was treated with ordinary remedies with little success. Baths, laxatives, and carbolic ointment did the most good. The skin being noticeably dry and harsh, and patient saying that she rarely perspired, it was thought that deficient action of the sweat-glands might be the cause, in part, of the peripheral irritation. She was put upon ext. jaborandi fluid, ℥. v., t. i. d., with almost immediate relief. Two months later she returned, saying she had been free from urticaria and pruritis, but that when she left off the jaborandi it returned. She felt perfectly well. The dose given made the skin slightly moist, but caused no other symptom.

HEROIC TREATMENT IN DIPHTHERIA.—Dr. Justin Hayes, of 167 Wabash Avenue, Chicago, writes, referring to an editorial discussion of the treatment of diphtheria:

"I am rejoiced that you have ignored and placed beyond discussion the expectant treatment in diphtheria. It should be as heroic as the treatment for venomous snake-bites, congestive chills, or cholera. When this is done there is no doubt about the success if the treatment is commenced in proper time—before the collapsed stage occurs, and then some cases may be saved."

Dr. Hayes states, that thirty-seven years ago, when a medical student at Slatersville, O., a malignant epidemic of diphtheria appeared there. His preceptor, in the treatment of his first cases, bled them, gave them alterative doses of mercury and depletants. His patients died in from thirty-six hours to four days. He changed his treatment to a tonic, antiseptic, sudorific, and stimulating treatment. With this they all recovered and were out of danger in about the same time the others died. Acting upon suggestions received then, modified by later experience, Dr. Hayes adopted a treatment which he has employed with success for many years. It consists in a very steady supply of powders (containing quinine, potas. chlorat., and piperin), cordial (containing camphor, chloroform, lavender, etc.), tincture of iron with a gargle of potas. chlorat., tinct. capsici, cardamon co., and camphor water. When the stomach can not retain medicine, it is given by enema and rubbed into the neck and chest.

A NEW REMEDY FOR INTERMITTENT FEVER.—Dr. R. Reiche calls attention (*Wiener Medizinische Zeit.*), to the value of the *flores siliginis* in intermittent fever. In Hungary, the blossoms are used as an abortifacient.

IPECAC IN ASTHMA.—Dr. Ide reports (*Allgemeine Medicin Central-Zeitung*) a case of asthma in a young woman, aged twenty-one. She has suffered since childhood, a good deal of bronchial catarrh being present. The case rapidly improved under small doses of tr. ipecac. The medicine was then left off for fourteen days, when the symptoms returned mildly. They disappeared again on resuming the medicine.

CEREBRO-SPINAL MENINGITIS IN THE NEW-BORN.—M. le Dr. Bambas has communicated (*Progrès Medicale*) to the Medical Society of Athens, an interesting case of epidemic cerebro-spinal meningitis occurring in the new-born. The mother died of the disease a few hours after the birth of the child. The disease attacked on the same day the infant, which quickly succumbed.

LEGISLATING AGAINST OPIUM DENS.—The State Legislature has passed the following law: "Every person who opens or maintains, to be resorted to by other persons, any place where opium, or any of its preparations, is sold or given away, to be smoked at such place; and any person who at such place sells or gives away any opium, or its said preparations, to be there smoked or otherwise used, and any person who visits or resorts to any such place for the purpose of smoking opium or its said preparations, shall be deemed guilty of a misdemeanor, and upon conviction thereof shall be punished by a fine not exceeding $500, or by imprisonment in the penitentiary not exceeding three months, or by both such fine and imprisonment.

A NEW HOSPITAL.—A plan has been filed in the Building Department for the erection of a hospital building for the Sisters of Charity, on the south side of West Twelfth Street, eighty-two feet east of Seventh Avenue. The building will be four stories and basement high, and will cost $150,000.

IODOFORM IN DIABETES is an effective remedy in large doses, according to Prof. Jac. Moleschott, of Rome (*Wiener Medizin. Wochenschr.*). Moleschott's formula is:

Iodoform	1.0	grammes.
Ext. lactuc. sat.	1.0	"
Cumurin	0.1	"

Div. in pil. No. XX. Sig., j. to iv. pills twice to four times a day.

The cumurin, an anhydride of cumaric acid, $C_9H_6O_2$, is claimed to disguise the odor best of anything.

THE GERMAN CONGRESS OF SURGEONS met at Berlin May 30th, under the Presidency of Professor Langenbeck.

Original Communications.

ON SOME NEW METHODS OF TREATING HYDROCELE.

By ROBERT F. WEIR, M.D.,

ATTENDING SURGEON TO BELLEVUE AND NEW YORK HOSPITALS.

The usual method of treating hydrocele is by the injection of tincture of iodine into the sac of the tunica vaginalis, as suggested by Sir Ronald Martin, in 1832. This method is a very safe and, speaking generally, a successful one. Certainly it has met with the approval of the profession more than any of the other methods of injection, such as of alcohol, of port wine, sulphate of zinc, etc., and possesses advantages in regard to the small amount of inflammatory action, over the use of setons, of cutting into the hydrocele, or of removing a portion of the wall of the sac. Nevertheless, it is followed by quite a number of failures,[1] especially where the weakened tincture of iodine has been used, or where the surplus tincture has been allowed to flow out through the canula, as is advised by some of the British surgeons. Mr. Samuel Osborn, in a little work on hydrocele, published in 1878, found that, in fifty-four cases of the affection, treated by tapping and injection, eighteen had recurrence of the trouble. My own failures have not attained such high proportions as this, a circumstance perhaps due to the fact, that not only was one to two drachms of the ordinary tincture of iodine thrown into the sac of the tunica vaginalis and there left, but also, following the suggestions made by my preceptor, the late Dr. Gurdon Buck, the inflamed scrotal tissues were, on the second or third day, rubbed and manipulated quite roughly, in order to intensify the inflammatory action, it being held by this distinguished surgeon, that the injection of iodine failed by reason of too little inflammation.

Upon the advent of Listerism an old method was revived, deprived of the dangers of inflammation by the use of carbolic acid, by Professor Volkmann, of Halle, who reported, in the *Berliner Klinische Wochenschrift*, 1876, seventeen cases of hydrocele, treated by free incision of the sac under antiseptic conditions. The following are the details of the operative proceedings:

"The genitals and inguinal regions are carefully and repeatedly washed with a solution of carbolic acid, and the skin of the pubic and perineal regions is closely shaved. Then, under the carbolic acid spray, the sac of the hydrocele is incised from the region of the external abdominal ring to the most dependent part of the affected side of the scrotum. The exposed and emptied cavity of the tunica vaginalis is next syringed out with a three per cent. solution of carbolic acid, and the edges of this incised membrane are stitched carefully to the corresponding edges of the incised skin by fifteen, twenty, or even more sutures of very thin silk. All bleeding vessels are ligatured by fine carbolized catgut. The antiseptic dressing is applied closely and firmly, so as to maintain the inner surface of the parietal layer of the tunica vaginalis in direct contact with the surface of the corresponding testicle, a small portion of this organ, however, being left exposed between the gaping edges of the incised wound. The prolonged action of the cold carbolic acid spray on the surface of the scrotum during the application of the sutures, and the repeated injection of a cold fluid into the sac of the hydrocele, cause considerable retraction of the dartos, so that this cavity becomes much reduced in size, and its membranes closely surround the testicle. In cases where the sac is very large and lax, and also in cases where there is much fibrous induration and sclerosis, it may be necessary to excise a portion of the tunica vaginalis. The most favorable cases are those in which the extent of the sac is so far reduced by the contraction of the scrotum that a small streak of the testicular surface is left distinctly visible between the edges of the wound. The introduction of a drainage-tube is not always necessary. In some cases, however, where a portion of the tunica vaginalis forms an elongated funnel, with valvular folds on its internal surfaces, a small drainage-tube should be passed as far as the front of the testicle. The blood having been removed from the seat of operation, the scrotum is surrounded by eight or nine strips of antiseptic gauze, and a large piece of gauze, in eight layers, with a corresponding slit in each layer for the passage of the penis, is placed over these. This dressing is closely maintained in its place by a bandage of gauze saturated with carbolic acid. All gaps in the dressing are stopped with portions of salicylized wool, and a large pad of this material is placed in the perineum, between the anus and the scrotum. Absolute antiseptic sealing of the wound is a necessary condition of total occlusion of the sac. On the first change of the dressing, the cavity will be found to be quite occluded, and the wall of the hydrocele-cavity closely adherent to the surface of the testicle."

These seventeen cases were subsequently increased to sixty-nine in a report of Dr. Genzmer in Volkmann's *Klinische Vortrager*, No. 135. In none of these was there any excessive inflammation, and the average duration of the stay of the patient in the hospital was ten days. The tube, if any was used, was removed generally about the fourth day, when the silk sutures were also taken out, and the dressing changed a second time at the end of a week. The wound was then dressed with the salicylized cotton batting inside of a suspension bandage, and the patient discharged.

I can corroborate the satisfactory progress of patients treated by this method. I have now resorted to this procedure some twenty-eight times, and in but two instances they have all proceeded as satisfactorily as above indicated by Volkmann. In these two, through error of manipulation on the part of my house surgeon, who performed the operation, there was too much stripping up of the skin from the subjacent tissue and some slight sloughing took place. The dressings were removed on an average about the eighth or tenth day. To promote the final healing of the little linear wound which was then left, a solution of nitrate of silver, five grains to the ounce, was painted daily on the granulations, as has been suggested by one of the German sur-

[1] Erichsen says: "Useful as the iodine injection is, it sometimes fails in producing a radical cure of hydrocele," and again, "it is by no means improbable that the success of the iodine injection in this country might not prove to be quite so great as is generally believed." —(Syst. of Surgery.)

Curling says: "Iodine injection is not capable of effecting a cure in every case." He also admits the painfulness of the injection which is quite frequently encountered, and suggests the use of an anæsthetic. —(Diseases of Testes.)

Agnew believes that the failures, when they occur, are due to the wrong use of the injection. The undiluted tincture of iodine should be thrown in and allowed to remain.—(Princ. and Pract. of Surgery, vol. ii.)

geons. This method has also been used with satisfaction in two cases of hæmatocele.

On reasoning out this process it is evident that after the evacuation of the fluid of the hydrocele, the flushing of the serous membrane by a solution of carbolic acid, the drainage-tube and the antiseptic dressing are the essentials of the operation. Now, in the hope of avoiding an extensive incision, I subsequently modified this procedure of Volkmann in the following way: the hydrocele was evacuated by a large size trocar and through the canula, held *in situ*, a solution of one to fifteen carbolic solution (adding a small quantity of glycerine to perfect the solution of carbolic acid) was injected so as to wash out the cavity thoroughly. A small, rubber drainage-tube was then introduced through the same canula before the latter was finally removed. This was done without ether, but under the antiseptic spray and other precautions. The usual Lister dressing was then applied, carbolized jute being substituted for the salicylated cotton in use in Europe. The drainage-tube was removed on the third, fourth, or fifth day, when the dressing was changed, and at the end of a week the antiseptic precautions were abandoned. My experience embraces some ten[1] cases in which this has been performed with satisfactory results, and in only one was there any inflammatory action, which was due to the patient's persistent disturbance of the antiseptic dressings. Though this plan was an improvement upon Volkmann's operation, it was yet hampered by the necessity of the use of the spray and antiseptic dressings. The fact, however, became patent, by resorting to these injections that they were free from pain, and I was, therefore, prepared to accept a statement that came to my notice in the Philadelphia *Medical Times* of the issue of November 6, 1880, by Dr. R. J. Levis, who advised that hydrocele be treated by the injection of a small quantity of pure carbolic acid into the sac of the tunica vaginalis, a procedure that he stated he had used since 1872. His method is to withdraw the fluid by an ordinary trocar, and then to introduce the long, slender nozzle of a syringe through the canula into the vaginal sac. By this means the carbolic acid is readily thrown into the serous cavity, and there is no danger of its being injected into the cellular tissue of the scrotum. The carbolic crystals are liquefied by slight heat or by the addition of a few drops of glycerine. The amount of carbolic acid which Dr. Levis injects is one-half a fluid drachm, and this is allowed to remain permanently in contact with the tunica vaginalis. The operation, he further states, is almost, if not entirely painless, because of the local anæsthetic action of the carbolic acid. Patients sometimes exclaim at the moment of the introduction, but complain of a sense of numbness, rather than of pain. The pain is certainly much less than where tincture of iodine is employed. Care, however, should be observed to allow no acid to flow upon the surface of the scrotum, for pain and inflammation will follow such contact. Dr. Levis had never seen suppuration or sloughing follow this manner of dealing with hydrocele.

I was led, during the early portion of last winter, to adopt this mode of treatment, and though prepared by my previous experience to believe that the carbolic injections were not very irritating, yet I was most agreeably surprised to find that the strong acid was, in the instances which have come under my notice, absolutely painless, or so very slightly so as to be insignificant. In my services at Bellevue Hospital, as well as in private practice, I have used this injection in thirteen patients, four of whom had double hydrocele, with only one failure. In the male hydrocele both sacs were injected at the same sitting. In this instance there was reaccumulation, and a second injection of the pure carbolic acid, two weeks later, was followed by a cure. In this action I afterward learned how to precipitate, for the fluid, when reformed, will gradually disappear, as after an iodine injection. In a majority of instances there was not such a reaccumulation of fluid, but there was considerable thickening of the whole tunica vaginalis, both parietal and visceral. This thickening will last three or four weeks, sometimes longer. Patients are at no time incapacitated from attending to their usual vocations, though Levis speaks of their being detained a day at most from such. In every instance the urine was carefully tested for three or four days subsequent to the operation, in order to determine whether or not there had been absorption of carbolic acid. None was observed in any case. The quantity injected was one-half to one and one-half drachm.

I feel warranted, therefore, from this experience, in corroborating the favorable judgment passed upon this method of treatment by its promulgator, Dr. Levis, and in presenting it as a procedure safe and painless, and, so far as my limited number of cases go, effectual in its results.

No. 37 West Thirty-third Street.

[1] Six of these have been already reported in the N. Y. Medical Journal, December, 1880, p. 631.

THE VACCINATION QUESTION.[1]

By P. C. BARKER, M.D.,

MORRISTOWN, N. J.

When we review the history of medicine during the past fifty years, especially when we contrast the present state of medical knowledge with that which obtained early in this century, it seems remarkable that so little has been added to what Jenner knew and taught us of the value of vaccination as a prophylactic against the ravages of small-pox.

It has been the hope of each generation, since his day, that our profession would so successfully oppose this great scourge of former times that variola would become a thing of the past; and it behooves us, at the present time, to pause and consider why it is that vaccination has not fulfilled this ardent and reasonable hope. Jenner closed his third memoir as follows: "May I not congratulate my country and society at large on their beholding, in the mild form of cow-pox, an antidote that is capable of expelling from the earth a disease which is every hour devouring its victims, a disease that has ever been considered as the severest scourge of the human race?" Seventy-eight years later John Simon, medical officer of the Privy Council, testified as follows concerning it:

"The belief which governs the vaccination system of this country (that properly performed infantine vaccination, duly renewed at puberty, will virtually extinguish small-pox as a fatal disease among such populations as have recourse to it) has rested on so vast a basis of well-established facts as not to have needed, for scientific completeness, that any further facts should corroborate it."

[1] Read before the New Jersey State Medical Society, May 24, 1882.

This belief has been universal for many years among those who were competent to form any opinion on the subject; and yet, neither in England nor in this country, has there ever been a prolonged period without its epidemic of small-pox, nor has there ever been a time during all these years when vaccination of some kind, performed in some way, has not been generally practised as a professional duty. In selecting this subject for your consideration, I have been influenced by a strong conviction that the public ought to be better protected by vaccination against small-pox than it is now or ever has been; by the hope that I may be able to point out some errors which have attended its performance in the past, and to indicate how we can so amend our vaccination system and practice as to "virtually extinguish small-pox as a fatal disease."

It is extremely doubtful if the public in this country is now as well protected against the spread of this disease, even in large cities, where boards of health furnish gratuitous vaccination to all comers, as it was fifteen years since without them. This statement does not rest upon the assumption that our boards of health are useless, nor that they have neglected to perform primary vaccination, or revaccination, but is based upon other considerations, which will appear in due time as we proceed.

Jenner named this bovine disease "variolæ vaccinæ," or small-pox in the cow. We have no better name to bestow upon it to-day. Experiment has demonstrated that the cow may be so variolated that genuine vaccinia will result, and the microscope testifies in favor of the essential identity of variola and vaccinia.

Jenner was well aware of the fact that primary vaccination could not be expected to last a lifetime, and cited cases in proof. In one of them (Case IX.) W—— Smith, first contracted kine-pox in 1780, caught it again in 1791, and the third time in 1794. Jenner did not consider that Smith's continued susceptibility to vaccinia was proof that he would probably have contracted small-pox. Indeed he expressed a doubt, and gave a case to illustrate the proposition, that a person might be susceptible to vaccinia and at the same time insusceptible to small-pox. A girl who had kine-pox in 1759, was ineffectually inoculated in 1797, and got vaccinia again from the natural source in 1798.

Jenner described the severe effects which often follow the use of lymph from a spontaneous vesicle, and contrasted them with the milder, more uniform and therefore the more reliable results obtained by using humanized lymph. These considerations, added to the conviction that the latter was just as "efficient" as the former, finally decided the question in Jenner's mind in favor of arm-to-arm vaccination. For about seventy years the world used lymph which had mostly descended directly from Jenner's stock. In this country, Dr. Valentine Seaman, of New York, and Dr. Waterhouse, of Boston, both procured lymph from Jenner in 1800; and it is probable that the lymph in general use in this country during all the years that intervened between that period and the introduction of the French bovine stock, was derived from these two sources.

It seems to be supposed by some writers on vaccination that Jenner did not think it necessary to introduce lymph at more than one place, but he makes no such statement in any of his writings, and we have evidence to show that he did not consider one insertion sufficient. Among the illustrations in his memoir, there was a child's arm showing a group of three vesicles, beautifully drawn and colored, and strikingly true to nature. Further corroborative evidence is found in the fact that it was for many years common practice in England to make three and even more insertions. Indeed it was to improve upon this very practice that Mr. Bryce suggested his method.

Bryce was the first to introduce vaccination into Scotland. In 1802 he published the details of a modified form of vaccination which he claimed would afford better protection than the one in general use. He expressed his reasons for employing his method as follows: "Inattention to this circumstance, viz., that the action of the virus of cow-pox may be often merely local, has been a fruitful source of error and disappointment in conducting the new inoculation." In another place he says: "If on the one hand we judge that the cow-pox affection has been complete when it has been only local, the person will be left exposed to all the horrors of the natural small-pox, which a false judgment given, of absolute security from the disease, had taught him to despise. And if, on the other hand, we judge that the cow-pox affection has been merely local, when it has in reality been general, we are induced to repeat the inoculation again and again; and, as the appearance of each of these re-inoculations will vary and a regular vesicle nor fever ever be produced, the same uncertainty will remain, until at length the inoculation for small-pox itself comes necessarily to be performed." To obviate all "uncertainty of action" his plan was as follows: Several days after a primary single insertion had been made, as soon as any activity was manifested, he introduced the second. A few days later, if the second showed any indications of succeeding, he repeated it a third time, and so on until they came to nothing. The peculiarity of this method consists in the fact that as many of the insertions as come to anything at all mature "consentaneously," the later ones overtaking the first.

The opinion has already been expressed that vaccination as practised many years ago afforded more complete protection than it does now; and I will add, than it has done at any time since 1869.

Going back to the old records we find that, from 1750 to 1800, before vaccination came into use, 9.6 per cent. of mortality from all diseases in London was due to small-pox.

From	1810	to	1820	it was reduced to	3.2	per cent.
"	1830	"	1840	" " "	2.3	"
"	1840	"	1850	" " "	1.8	"
"	1850	"	1860	" " "	1.2	"

Taking the death-rate of small-pox alone for the London epidemic of 1818 to 1823, only one in every 330 vaccinated people died, while in the epidemic of 1876–79 one in 28 died. This includes people who had been vaccinated in any way, or who said they had; and shows that many more people were savingly protected in 1820 than in 1876.

W. F. Jebb, clerk of the Metropolitan Asylum, of London, reported that, from the autumn of 1876 to October 31, 1879, 15,171 cases of small-pox were treated in the various hospitals of London. Of these, 11,412 had been vaccinated, and 3,759 had not. Out of the whole number of cases, 2,677 died. Of the vaccinated there were 1,008, and of the unvaccinated 1,669.

The report of Dr. Buchanan, for the year ending May 25, 1881, gives a total of 1,532 fatal cases. He calculated that there were in London 190,000 unvaccinated persons, 105,000 being under twenty

years of age, and 41,000 under five years of age. One inspector, going from house to house, reported that, out of a total of 6,018 children, he found 828 unvaccinated.

England has been more or less under the influence of compulsory law since 1854, and there have always been men like Ceely and Marson and Seaton and Simon, and many other advocates of thorough vaccination, who have earnestly endeavored to secure the best and most efficient system and organization for its due performance; and yet there are still large numbers of people in England who are entirely unprotected by vaccination, and, what is still worse, statistics show that, among those who are supposed to be efficiently vaccinated, there is a considerable percentage of fatal cases of small-pox.

In the United Kingdom there are six hundred and forty-seven "Boards of Guardians," as they are called. Under these various boards are nearly four thousand practitioners who act as public vaccinators. About seventy per cent. of all vaccinations is performed by them. The fault, therefore, does not lie in the imperfection of the machinery, but in the details of its operation; as well as in other causes which have thus far seemed to be unavoidable, being due to the ignorance, heedlessness, and blind opposition to vaccination that characterize the population of the worst quarters of all large cities. It is a well-known fact that most epidemics have their origin in and spread from these centres of contagion.

These obstacles to the successful suppression of small-pox are important, and demand serious consideration; but they are not the only causes of failure, nor are they the ones which most affect us as sanitarians. As Mr. Simon wisely says, "No principle can be more obvious than this: that if the State professes to vaccinate the people, above all if it compels the people to be vaccinated, it must take every possible security for the excellence of the vaccination which it offers." . . . "What has to be administered is not a mechanical matter of routine and registration; but a system which, from beginning to end, and from centre to circumference, requires *in all its parts to be vitalized by the science of medicine.*" (The italics are my own.)

Complaints have been made in English medical journals from time to time, for many years past, that primary vaccination had been performed without due regard to the quality of the virus, or the number of insertions necessary to insure its full protective power. Marson, of the London Small-pox Hospital, during thirty years' experience, had under his observation more than 15,000 cases of variola, which were carefully studied, classified, and recorded. He found a marked and definite relation between the number and character of the cicatrices and the number of cases that occurred among the vaccinated. Of the latter there were, having one vaccine cicatrix, 7.73 per cent.; having two vaccine cicatrices, 4.70 per cent.; having three vaccine cicatrices, 1.95 per cent.; having four or more vaccine cicatrices, 0.55 per cent. Of all these, again, there were, having well-marked cicatrices, 2.52 per cent.; having badly marked cicatrices, 8.82 per cent. There was another point of interest and importance, in connection with the cases having but one cicatrix, showing the difference in protective power between a good and a poor one. Where the cicatrices were of good size and well foveated, the death-rate was only 3.83 per centum; while among the small or indistinctly marked cicatrices, the rate was 11.91 per centum. It should be remembered that these cases were all primary vaccinations, except nineteen who had previously had small-pox.

Small-pox records have not been kept in this country, either long enough or with sufficient detail and precision, to serve as data for such an investigation as the present, and it will be observed that I have drawn mostly from English sources. Great Britain has the advantage of us in another respect, namely, in having compulsory laws and a vaccination system; and it is highly probable that vaccination is more generally practised in the rural districts and small towns of England than in corresponding communities in this country; but that is not saying that the English people, who are vaccinated, are any more perfectly protected than are our own people; nor do I think that such is the fact, for revaccination is probably more generally practised here than it is in England. So far as our statistics enable one to compare the general results of vaccination, in the two countries, there seems to be little advantage on either side.

The fact is that, neither in England nor in this country, is vaccination "vitalized by the science of medicine." With most practitioners in this country it is a disagreeable duty which must be performed. Consequently, it is attended to in a perfunctory manner, often with lymph procured at any stage of development of the vesicle; and then it is forgotten or, at least, left to run its course unwatched. No other duty devolving upon the physician is of more importance to the welfare of the community; and no other minor operation in these days of Listerism is left to the chance of septic or other untoward influences.

Reference has been made to the difficulty of inducing the ignorant parents, of children born in large cities, to have vaccination performed. The health authorities in our cities have always had to contend against this prejudice. In Brooklyn, during the years 1870 and 1871, there were 1,068 cases of small-pox, with 408 deaths. Of these, 69 per cent. occurred in unvaccinated children under two years of age, although there was a regular corps of public vaccinators, who had been from house to house, in their respective districts, and vaccinated every child whose parents would permit it. They met with stubborn resistance in the worst wards, and succeeded only, by patient explanation of the value of vaccination, and by carefully looking after those who had been vaccinated to see that it ran its course kindly. By this means a better state of feeling was sometimes established, and the vaccinator was asked to vaccinate children in houses from which he had previously been repulsed.

The New York Board of Health inaugurated house-to-house visitation in 1869, with a corps of sixty physicians. Their system has been in constant operation ever since, and they have taken great pains to vaccinate every infant and unprotected person; and yet, during the year ending March 20, 1872, there were 337 cases of variola in children under five years of age, and 113 of these exhibited indications of previous vaccination.

Through the kindness of Dr. J. B. Taylor, of the New York Health Department, I am able to add the following statistics for the year 1881: During the year there were 1,342 cases of small-pox in New York City; of these, 799, or 59.5 per cent., had been vaccinated, while 543, or 40.5 per cent., had not. There were 404 deaths, 137, or 33.9 per cent., had been vaccinated, and 267, or 66.1 per cent., were unvaccinated. There were in all 490 children under

fourteen years of age. Between eight and fourteen years there were 79; and under eight there were 411, or nearly 84 per cent. of the whole number of children. Only 16 of the 411 had been vaccinated, while 393 had not. Among those whose ages ranged between eight and fourteen, 48 had been vaccinated, and 31 had not.

These 424 cases of unvaccinated children who contracted small-pox in New York City last year, illustrate the failure and danger of the persuasive system of vaccination; just as the 66 cases which occurred in vaccinated children show certain other defects which will appear further on. It should be added in this connection, that none of the vaccinated children died.

Among the whole number of vaccinations performed during the year there were 148 complaints of bad results following the use of the bovine lymph. Of these, 38 gave trouble in healing, and there were 19 abscesses.

Disappointed in the fact that vaccination had failed to prevent recurrences of epidemic small-pox, and fearful lest other diseases than vaccinia might be communicated by humanized lymph, certain members of the profession many years ago began to advocate the adoption of retrovaccination, and of bovine cultivation of lymph. At the Medical Congress held at Lyons in 1865, Palasciano, of Naples, announced that he had for some time been vaccinating with bovine stock which he propagated from calf to calf. Lanoix, of Paris, was much impressed by his statements, and went to Italy to study this calf culture of lymph. Upon his return to Paris he took a vaccinated calf with him and opened an establishment. About the same time a spontaneous case of cow-pox was discovered at Beaugency, near Orleans. Within a period of fifteen months 9,319 vaccinations and revaccinations were performed with Lanoix's stock. Of the former about fifty per cent., and of the latter sixteen to seventeen per cent., were successful. The incubation stage varied (in children) from five to twelve days.

These results were carefully watched by the two factions in Paris, one headed by Depaul, the ardent champion of bovine lymph, and the other by Guérin, who adhered with equal fervency to the old stock of humanized Jennerian lymph. Bitter and noisy was the wordy contest in the Academy of Medicine between these opposing parties. Depaul and his ideas finally carried the day, and bovine virus gradually came into general and almost universal use, not only in France but throughout the civilized world.

Notwithstanding the claims of the propagators of and dealers in bovine lymph to the contrary, I believe that no better results can be shown to have followed its use in this country than those obtained by M. Husson with Lanoix's lymph, in Paris, as quoted above.

It is not denied by any of the advocates of bovine stock that a certain proportion of the vesicles yield inert lymph.

Moreover, the character and development even of a genuine bovine vesicle duly charged with corpuscles, is quite different from one produced by humanized lymph, during its whole course. Ignoring for the present the increased amount of local disturbance usually manifested by the former, the annular elevation of the lymph-cells is less, the cells are more likely to be broken, and the bovine crust is lighter in color, thinner, and more friable. A good humanized crust is of a rich brown color; semi-translucent when held up to the light; and its thickness, according to Dr. Loines, should be nearly one-third of its diameter.

If we compare the reliability of the two kinds of lymph, as indicated by the ratio of success attending the first trial, still greater differences will be found. From 1856 to 1866, in London, about seventy per centum of all infants were vaccinated, and of these 98.9 per cent. were successful on first trial. Dr. Seaton reported that 446 points of Jennerian virus were obtained from the National Vaccine Institution and were distributed to five different vaccination stations. Of these 443 produced typical and perfect vesicles. The best results of the vaccination corps of the city of New York, in 1869 and 1870, was about ninety-eight per cent. of success on first trial. In Philadelphia, in 1869, 41,444 were vaccinated by public vaccinators, with a failure of only 1.25 per cent. on first trial.

In Brooklyn, during the years 1870 and 1871, some of the most experienced of the corps had only one failure in every 243 vaccinations.

There has been much talk during several years past in certain quarters about "pure animal virus;" and it is a significant fact that every one of the thirteen propagators in this country claims that he alone has it. As a matter of fact, I believe that there is not more than one among them all whose stock has continuously descended from calf to calf without admixture with some other stock; or that has not been more or less times cultivated in the human circulation since it was derived from its natural source. One of these dealers procured his stock from a case of spontaneous cow-pox, discovered in New York State in 1874, and he claims that he has himself cultivated it in the calf ever since.

Viewed in the light shed upon contagious diseases by the "germ theory,"[1] and especially by the

[1] The germ theory of disease has opened a new and important field of research analogous to vaccination, which it is hoped may yet result in additional triumphs for preventive medicine against other contagious diseases of mankind, as it already has in certain diseases of fowls and domestic animals. Pasteur's experiments in fermentation and putrefaction led to the discovery (in 1850) of the "bacillus anthracis" in splenic fever. Dr. Sanderson discovered, by experiments made in 1878, that the "bacillus" became so modified, by being propagated in the guinea-pig, that its introduction into the circulation of the cow, although followed by severe results did not prove fatal.

Pasteur here took up this line of investigation and succeeded in so modifying the virulency of the "bacillus" by repeated cultivation in chicken-broth, that its introduction into the circulation of the sheep was not followed by any severe effects, although his source of supply was the blood of a sheep that had died of splenic fever. Carrying the investigation still further, he found, by applying the *experimentum crucis* that these animals were not only protected against ordinary exposure, but that they were not disturbed by inoculation with the blood of an animal that had died of the disease. Other sheep, unprotected by "vaccination," as Pasteur calls it, which were inoculated with the same blood, died in fifty hours.

Animals worth four millions of dollars die annually of splenic fever in France. The authorities are vaccinating large numbers of sheep, as well as horses and cattle, with the cultivated "bacillus;" as many as twenty thousand sheep have been vaccinated in a period of fifteen days in the departments contignous to Paris alone; and the practice is becoming general throughout France.

The germ theory of disease assumes that all zymotic, contagious, and infectious diseases are propagated by what Beale has termed "*bioplasms*," which are minute living cells of animal origin; and which, perhaps, at some antecedent period may have been perfectly healthy.

It also assumes that neither "bacteria," nor "microzymes," nor "fungi," nor any other kindred form of life is concerned in the propagation or dispersion of any of the contagious diseases in man; and Beale includes animals. Pasteur's more recent experiments go to show that the latter statement may be taken with some reservation, as "bacteria" which are found in some of the infectious diseases of animals seem to be something more than a mere envelope for a bioplasm.

Applying the germ theory to our subject, we find that, if lymph be taken from a recent small-pox vesicle and examined with a $^1/_{25}$ inch objective (magnifying from 1200 to 1800 diameters), numerous clusters of spherical or ovoid bodies are seen, each having a distinct nucleus, a pale blue color, and the power of motion and division. These cells are the "*variolic bioplasts*," and in them resides the *contagium* of small-pox.

If lymph from a vaccine vesicle is taken at an early period in its de-

light which Pasteur's experiments have thrown upon the cultivation of disease-germs, we are at last in a position where we can formulate some scientific deductions. For instance, we would be justified in assuming, if we did not know, that the use of lymph direct from the natural source would be likely to be followed by more severe constitutional as well as local effects, than subsequent repetitions would produce. We are also justified in assuming that, as the "variolic bioplasm" has undergone no diminution of virulency by long transmission through successive generations of men; and as the "bacillus" can be indefinitely cultivated without any deterioration of protective power, so it is reasonable to suppose that the "vaccinad" will maintain its integrity and activity, if properly cultivated, even through indefinite generations of humanizations.

Nor is it difficult to believe that its protective power did continue for a period of seventy years, when we review the evidence which recorded observation has placed within our reach.

The report of the London Metropolitan Hospital, for 1879, stated that no case of small-pox had ever been observed by any of the superintendents of that hospital in any person "who had been efficiently vaccinated and successfully revaccinated." Moreover, there were but six cases in forty years out of over one thousand nurses and servants employed in the institution who had been affected in any way, and every one of these had in one way or another escaped revaccination before entering the wards. These persons had been vaccinated with lymph, many times removed from the original source, and it is evident that its protective power was unabated. Curschmann examined over one thousand cases of small-pox, and not one of them presented evidence of efficient vaccination. Dr. Loines, of the Eastern Dispensary, in New York City, performed 110,000 primary vaccinations in seventeen years. About 20,000 of these were opened and furnished over 400,000 quills. His revaccinations amounted to something over 90,000, and he never knew of a case of small-pox in any person he had pronounced well vaccinated. He made four insertions in a group, and inspected the arms on the eighth day (day week), and after the fourth week he examined the cicatrices. If satisfied, he gave the parents of the child a certificate. Dr. Ward, of London, was a vaccinator for more than forty years, and vaccinated about 48,000 people. None of these cases were known to have died of small-pox, although not 3,000 were revaccinated. For nearly forty years vaccination has been compulsory in the armies of Prussia, Wirtemburg, Denmark, and Sweden, with the result of almost completely extinguishing small-pox even in sporadic form from their ranks. With such evidence before us it is useless to claim that the Jennerian lymph, used in these cases at least, had suffered any kind of deterioration whatever, notwithstanding the probability that some of it was more than three thousand removes from the original bovine source.

There is no good evidence that this Jennerian stock had lost any of its inherent potential energy through all those years; and even if there were, I submit that the stock might have been renewed from the natural source from time to time, without changing the method of cultivation. In my opinion the substitution of this untried (bovine) method for an old and well proven one, was both unwise and unscientific; and I further maintain that events have demonstrated the fact.

The claims of the "syphilophobists," too, have proven to be equally unfounded. There is no good evidence that syphilis or any kindred disease was ever communicated in lymph, nor even that vaccinia and syphilis have been communicated at the same time. Experiments made with chancrous matter and lymph mixed together utterly failed to produce a combined action. Either vaccinia or syphilis resulted, one or the other and nothing else. Professor Sigmund, of Vienna, got nothing but syphilis in his experiments. In Dr. Loines's experience, large as it was, he never saw syphilis communicated by vaccination. Nor did Marson in his 40,000 cases, nor Luse in 40,000, nor West in 26,000, nor Sir William Jenner in 13,000 cases; and none of them believed that there is any real danger of communicating syphilis by vaccination.

What, then, I ask, are the special advantages of bovine cultivation, and the use of "pure animal virus?" I know of but one. In times when small-pox is epidemic, large quantities of lymph can be furnished at short notice. On the other hand, let us consider some of the disadvantages attending its use.

First.—Bovine lymph often fails on first trial, even in the hands of the best vaccinators.

Second.—It is irregular and generally tardy in its period of incubation.

Third.—It is often extremely difficult to tell from an inspection of the vesicle whether it is genuine (efficient) or not.

Fourth.—The local effects are, as a rule, severe; so severe in fact that he would be bold indeed who made four insertions in a young infant (as Loines habitually did).

Fifth.—Owing to the depth of its action, and the slough which so often follows its use, even the cicatrix does not afford definite information; as it does not under these circumstances show characteristic foveations. It is a mistake to suppose, as many do, that the extensive induration and redness which is often seen around the (bovine) vesicle is any measure or indication of its efficiency. On the contrary, it is a positive evil, being simply a mild septic inflammation of the skin and subcutaneous tissues produced by degenerated "bioplasts," pus-cells, or other improper material which has been conveyed with the lymph.

velopment and examined with the same high power, numerous clusters of cells, each bearing the same characteristics, will be found in abundance. After the eighth day, however, in both cases, some of the cells seem to have degenerated: and in this condition they resemble the pus cell in appearance, although of course they are very much smaller.

This perfect correspondence between these "*bioplasts*" is presumptive evidence of their identity; but it is not conclusive, for apparently identical "bioplasts" have been discovered as the accompaniments of other contagious diseases: and the fact still remains that neither the microscope, nor chemistry, nor any other known physical test enables us to recognize these cells, or to distinguish one kind from another; but improved methods or appliances in microscopy may yet demonstrate structural differences. Experiments made by Chauveau and others would seem to indicate, beyond any reasonable doubt, that the "*contagium vivum*" resides solely in the living cells, which are found in all the contagious diseases and infectious fluids of men and animals, and that a careful separation of these cells from even the most virulent fluid leaves the remaining portion perfectly innocuous. Chauveau states, in the most positive manner, that there is no question of this fact. He has repeated his experiments many times, and his statements have not been disputed, nor even questioned.

Vaccine lymph consists of serum, which contains, let us assume, the "*variolic bioplasm*" which has been modified by cultivation in the circulation of one of the bovine species.

Our object in vaccinating our patients should be to propagate this "*vaccinad*," as Farr called it, by cultivation in the human system, as a protection against the virulent and contagious "*bioplast*" generated in variola.

This is precisely analogous to vaccination with the "*bacillus anthracis*," except that the latter is, for convenience, cultivated in chicken-broth, instead of the guinea-pig; and, to carry the analogy still further, Pasteur thinks that the protective power is likely to be prolonged. In chicken-cholera, however, the case is different. He has known the protective power of this form of vaccination to be exhausted in one year.

Sixth.—The small lymph capacity of the bovine vesicle is notorious. Twenty quills is a good yield, while as many as eighteen hundred have been taken from a single humanized vesicle. If the vesicle in vaccinia is the analogue of the eruption in the various contagious diseases (and experiments made with lymph administered internally would seem to indicate that it is), this deficiency in development would point to a corresponding loss of protective power.

Seventh.—It is a reasonable deduction that, inasmuch as the "variolic bioplast" is in some way greatly modified by one cultivation in the circulation of the cow, every successive bovine transmission may modify it still more; and that in time its protective power may be lost entirely. Whether this conclusion be true or not, there is no good ground for the idea that long descent is any better for bovine than for humanized lymph; and the ordinary advantages which attend the use of the latter, as compared with the former, are certainly beyond dispute. It is my belief that the lymph in use at the present time, and that has been used for several years past, has less inherent protective energy than the old stock had, and that a careful scrutiny of statistics will satisfy any unprejudiced mind that many young children, with fair evidences of successful primary vaccination, have in recent years had small-pox and died from its effects simply in consequence of the depreciation of the lymph that has been in general use.

Returning once more to our belief in the fact that "properly performed infantine vaccination, duly renewed at puberty, will virtually extinguish small-pox as a fatal disease," we have still to consider the practical side of the question, *what constitutes efficient vaccination, and how can we make it efficient?*

While we are in complete ignorance as to the *modus operandi* of this "bioplasm," or any other in the system, still we do know a few facts concerning the laws that regulate the development and spread of the various contagious eruptive diseases, upon which we are in the habit of depending. Among other things, we know that a very mild case of any of these diseases will not be as likely to protect the subject against a repeated invasion as would a well-marked typical case. We also know that people vary immensely in respect to their susceptibility to contagious diseases of all kinds; and that with some this susceptibility is so marked that they may, and sometimes do, contract contagious disease repeatedly. Experience has shown that a certain amount of this unknown influence must be produced in the economy by vaccination in order to protect the person completely. Again, experience has taught us that one good vesicle may afford ample protection for a lifetime even. It has also demonstrated, as appears in Marson's much quoted tables, that two, three, and even four good vesicles may not afford full protection. In short, it is not the number of vesicles, nor even their perfection, that we are to depend upon, but a reasonable certainty that the system is so saturated with the lymph that it will take no more. This, as I understand it, constitutes efficient vaccination. Anything short of this may be, or it may not be, protective. For these reasons Bryce's method commends itself to us as the best, and worthy of general acceptance and practice. Indeed it is the only method by which the system can be known to have been saturated at any given time, whether by primary vaccination or revaccination.

Of no less importance is the lymph, which should always be taken at an early period, as soon in fact as it will flow from the cells. It is not only more active (reliable) at this time; but it is the only time during the development of the vesicle when it is absolutely free from degenerated corpuscles. Bearing this fact in mind, it follows, as a matter of course, that it should never be preserved in any way except on quills or ivory points which are clean and free from animal matter. Neither cells nor crusts nor capillary tubes, much less those questionable cones, should ever be used except in an emergency. We do not seek to convey either half-decomposed blood, desiccated epithelium, nor dried or other pus-cells; but "vaccinads," and them only, to the arms of our patients. Nor should we perform this important operation and leave the results to such untoward complications as we know by experience may intervene. The child should be carefully watched, especially to ward off any local inflammatory or septic influences. If we are "vitalized by the science of medicine" we will bear these facts in mind, and perform our vaccinations in accordance with them.

This leads me to remark that we would do well to place this whole matter in the hands of the State Board of Health, of the national organization; or of a National Board of Vaccination whose duty it should be to cultivate lymph and appoint public vaccinators, who alone should have the right to vaccinate or revaccinate. Vaccination is not only a science. It is an art! Dr. Taylor, of the New York Board of Health, stated to me that few among their corps became good vaccinators short of a year's experience; and that, while some required much more time, there were always a few who never became expert. Ex-Sanitary Superintendent Segur, of the Brooklyn Board of Health, testified to a similar experience. Nor do I see why vaccination should not be made compulsory, in a modified way, in this country.

In Germany, every child must be vaccinated before it is one year old, and revaccinated before it is thirteen. In the army, revaccination is practised at regular intervals; and with perfect success.

Italy, Austria, Bavaria, Sweden, and Scotland also have more or less compulsory regulations, some of them combining persuasive elements. In Austria the public vaccinator visits every house in his district; and those who refuse to avail themselves of his services are denied every kind of charity, admission to schools; or to hold any office; or to obtain any kind of public favor whatever. In Sweden, after two years' endeavor to induce parents and guardians to vaccinate, if they still resist, the authorities apply fines and other legal penalties. Their system works well. In Scotland, under the act of 1864, all infants are expected to be vaccinated within six months of their birth. If not reported to the Registrar, he sends a reminder. The result has been that small-pox has become almost extinct in the child population of Scotland. For the decade ending December, 1874, 96.18 per centum of all births were successfully vaccinated. With our State system of registration of births, we could easily adopt the practical workings of the Scotch system.

Providence, R. I., has long had a very good system. Their birth statistics are gathered by house-to-house visitation, and children are vaccinated gratuitously every Saturday. During a period of forty years there were a few cases of sporadic small-pox, but in no instance was there a second case.

Much might be urged in favor of compulsory vaccination laws; but I will simply reiterate my belief

that they are both necessary and expedient, and that we should use our best endeavors as members of the State Medical Society, and as individual promoters of sanitary science and preventive medicine, to get such laws enacted in our State at the earliest possible moment.[1]

FEEDING PER RECTUM.

As Illustrated in the Case of the Late President Garfield and Others.

By D. W. BLISS, M.D.,

WASHINGTON, D. C.

I PREFER this expression to those commonly in use (as "rectal alimentation," etc.), not only because it is more terse, but also because it more exactly describes what occurs, as will be seen farther on.

It has long been my desire to lay before the profession, not only the results of my own experience, but also the published accounts of others. The latter first caused me to explore, and afterward test for myself this artificial method of sustaining life. Extraordinary demands upon my time and strength have hitherto prevented any such attempt. The gravity and importance of the subject can scarcely be overestimated, while the history of its employment in both medicine and surgery is more interesting than any romance.

It will surprise many of the profession to learn that there is strong reason for the belief that, not only the history of enemata (*pur. et simp.*), but that of nutrient enemata as well, goes back to the ancient Egyptians, many hundred years before Christ (see Herodotus *Euterpe*, Cary's Transl., Am. Ed., p. 125, N. Y., 1855), from which it appears that they had a custom of using emetics and clysters three days in each month to preserve health ("Med. and Surg. Hist. of the War," part ii., p. 825). The Greek physicians also made great use of clysters in the treatment of fluxes, particularly the "cœliac flux," preferring this method to medication by the mouth. They used wine, whey, milk, ptisan, broth of spelt, and the like. Sometimes they aimed to sheathe the walls of the intestinal canal, and thus protect them against acrid humors descending from above, by injecting oleaginous or gummy substances ("Med. and Surg. Hist. of the War," op. cit.). In many instances these rectal applications not only were, but were intended to be, practically nutrient, in addition to their original use as aperients. If disciples of Hippocrates used the assimilable elements just alluded to, we must admit that rectal feeding has been a plant of very slow growth. Still, its study certainly exhibits one of the most interesting examples of the progress of thought and observation in the art of medicine.

In the narrow limits of this article it is manifestly impossible to give many excerpts from the authorities referred to. A full account of the materials used, of the mechanical means employed in administration, with reports of cases, would fill a large volume. It is therefore necessary to content ourselves with but a meagre outline, appending such references as are both interesting and important.

Probably the earliest form of syringe was that used by the Egyptians, consisting of a pipe with a bladder tied upon one end. The form recommended in the Hippocratic treatise ("De his quæ Uterum non Gerunt," edition Littré, viii., p. 431) differed from this only in having a number of little orifices in the sides of the pipe. From these primitive means resulted our present system, by which a continuous stream may be thrown to almost any point in the large intestine. All are acquainted with the so-called "fountain" syringe,[1] by which a continual drench of the lower bowel may be prolonged at pleasure. Longer pipes than those commonly used have proved valuable in many cases. In one instance (that of a distinguished senator, now dead), I was obliged to frequently introduce the tube of a stomach-pump very nearly the whole length of the transverse colon. There is small difficulty in this operation, save that a little awkward delay may occur at the sigmoid flexure. It is hard to imagine that any further improvement in our present instruments will ever be made or needed.

As to *materials employed*, while almost every article of food, the form of which admitted of injection, has been used—*e.g.*, milk, eggs, beef-broth, etc.—it is probable that the use of finely divided beef with pancreas has been known since the days of Hippocrates. Dr. Brown-Séquard (London *Lancet*, January 26, 1878) says, referring to an article by Dr. Kaufmann (*Deutsche Zeitsch. für prakt. Med.*, No. 44, 1877): "It is essential that the pancreatic gland which is to be used, be from an animal quite recently killed, as the tissues and juice of that gland lose their property very quickly if the temperature of the surrounding air is at all high. It is well to take away the fat and cellular (connective?) tissue, and inject only the meat and glandular tissue, very finely divided and thoroughly mixed." This statement, coming from a most eminent neurologist and pathologist, is interesting, first, because the venerable doctor has followed in his published statements one of the first accepted methods of alimentation *per rectum*; and second, because he evidently believes that pancreatic juice possesses a digestive power only rationally demonstrated by modern physiologists. Dr. Kaufmann, in the above citation, calls attention to the "excellent results obtained by feeding patients with pancreas and meat *per anum* in

[1] I did not contemplate making any allusion to erysipelas as a complication of vaccinia, but the remarkable statements of Dr. C. A. Lindsley, of the Medical Department of Yale College, communicated in a paper published in the last report of the Connecticut State Board of Health, seems to demand consideration. A reprint of his article is before me, and I will quote from it. On page 16 he says: "The occasional occurrence of erysipelas after vaccination with the Jennerian stock was an evil which no degree of prudence in the selection of the virus, study of coincident influences, or of the condition of the subject, could altogether guard against." In another place on same page he again says: "It is said that erysipelas is particularly liable to occur in revaccination with humanized lymph." He then goes on to quote Dr. Martin's evidence, given in the Boston Medical and Surgical Journal, for February, 1877, as the basis of the full and sweeping statement which he is now prepared to make, namely, "that erysipelas, which is the *pest* of humanized virus, does not occur at all after the use of bovine virus, *but that it is even prophylactic of erysipelas*." (The italics are partly my own.)

The published records of the New York Dispensary and the Kine-Pock Institution, show that this "pest of humanized virus" occurred in about one in five hundred cases. When we take into consideration the devitalized constitutions of many of these tenement-house children, who constitute the large majority of dispensary patients, the septic influences which always abound in charitable medical institutions, and the insanitary condition of the homes of these children, we might better wonder that only 0.2 per cent. of these minor operations was followed by erysipelas. The writer used the old Jennerian stock of lymph for seventeen years, and never had erysipelas or any other septic influence follow its use, while he has since had several cases of erysipelas and very many mild cases of local septic inflammation as attendants upon the action of bovine lymph.

There were several cases of erysipelas among vaccinated infants in Brooklyn last year, just how many I have been unable to ascertain; and one of them at least proved fatal. Seven cases were reported to the New York Health Department. Dr. Taylor wrote me that "the report may not be very trustworthy, as it is possible that all cases were not reported." He added that it is his opinion that very little erysipelas prevailed in the city last year, and that very much more might be expected this year.

[1] See Mem. Med. Society Journ., description by J. Bureau, 1794, vol. ii., p. 234.

cases of persistent and incurable intestinal obstruction." He states that he had nine patients in the Kölner Bürger Hospital, seven of whom were suffering from cancer of the œsophagus, one from cancer of the pylorus, and one from chronic gastric ulcer. In all these cases a cleansing injection was administered in the morning, followed by finely divided beef and pancreas (1 lb. beef to ½ lb. pancreas), the whole being freed so far as possible from fat and connective tissue. One-half this quantity was used at noon, and the other at 6 P.M. Results excellent. Solid, well-formed fæces were discharged each day. Patients were able to walk about, and lived in this way an average of nine months, or more.

In the list of authorities subjoined, direct or indirect reference is found to more than four hundred cases. The treatment, so far as materials used is concerned, is substantially the same. In by far the largest number enemata of eggs, milk, and beef-broth, with and without stimulants, were given. Defibrinated blood was also used in some instances, but there seems to have been a general experience of difficulty arising from the strong tendency of blood to decompose in the rectum. My friend Dr. A. H. Smith reports eleven cases in which the blood alone was used, and in which assimilation failed in only one case. In that case the odor emanating from the patient became so offensive as to pervade the whole house, and require a suspension of its use.

I am unable to fix the exact date of the first use of defibrinated blood. Reports upon this form of injection are found in "Proceedings of the Therapeutical Society, New York, 1878," xxviii., p. 81, and in *New York Medical Journal*, 1879, xxix., p. 404. The second report says "the material for this paper is extremely meagre, consisting only of two experiments by myself and six cases—three by myself, two by Dr. Douglass, and one by Dr. Hadden." The report in "Proceedings of the Therapeutical Society" mentions sixty-three cases successfully treated with blood. It is impossible to specially describe these interesting cases in this article. We therefore note that in dysphagia, septicæmia from wounds, cancer of the pylorus, and in cases of malnutrition by the stomach from various causes, blood was found very useful, unless undue irritability of the rectum prevented the retention of the enemata. Dr. Andrew H. Smith, in the *Archives of Medicine*, vol. i., 1879, recounts eighty cases, of which there were only two or three where rectal irritation was sufficiently great to cause a return of the injections of blood. The conclusions of this distinguished physician I brief as follows: That defibrinated blood is admirably adapted for use in rectal alimentation. Doses of two to six ounces given once or twice daily produce more or less constipation, which in a small number of cases becomes persistent. In a very small number of cases irritability of the bowels attends its protracted use, but was unaccompanied by dangerous or even serious symptoms.

There is no doubt that the use of this material, properly prepared, was a step in the right direction; but more remained to be done. An interesting article in the *Journ. de Thérap.*, Paris, 1880, vii., p. 846, describes some observations on the use of dried beef's blood ("Le Sanguis bovinus exsiccatus et l'hémoglobine"). These, with other reported cases, prove that cooking by chemical or other means is necessary to the best success. Yet it is curious that, as late as 1878, one of our most eminent authorities declares that "whatever may be the explanation, clinical observation fully establishes the fact that the digestion of animal broths, milk, and eggs, takes place in the rectum, without the addition of pepsin and hydrochloric acid."

It is interesting to note the great variety of nutrient and stimulating enemata recommended at different times. Hot injections, cold (P. Dagaud: "Action physiologique, et usages thérapeutiques des lavements froides," Paris, 1879), of medium temperature, and of almost every conceivable composition, from red wine to elaborate mixtures of bouillon, eggs, milk, and stimulants are in the list. Even enemata of tobacco smoke are mentioned in 1756 (G. A. Languth: "Candid. Joan Ludov. etc. Henne Wittembergæ"). The earliest mention of pancreatic enemata with which I am acquainted is in 1671 (in "Tractatus Anat. med. de succi pancreatici matura et usu," p. 216, Batav.).

Nutrient suppositories are described in the *St. Louis Surg. and Med. Journ.*, April, 1882, p. 419, referring to the *British Med. Journ.* of February 19, 1881: "Artificially digested meat is mixed with a little wax and starch, and made into a suppository. They are of such a size that the digested and extracted product of twenty ounces of meat, from which the insoluble matter is removed, is contained in about five suppositories. The convenience of this method is very great. It is easy for most patients to introduce them themselves, and their use is attended with no discomfort whatever, in the majority of cases. After an hour or two the waxy basis is frequently returned, the peptone and extractive being absorbed. In some cases, owing to irritability of the rectum, the whole suppository has been returned; but this can be obviated by the addition of a little opium to each suppository."

In the case of the late President Garfield we were enabled, through the kindness of Dr. Smith, to use specially prepared blood. It was found, however, that the same trouble arose as in the last case cited under this head, and we were forced to discontinue it. Whether this result was due to the general debility of the patient or to the unstable nature of the substance used, I cannot say, but it is probable that both causes contributed. It is certain that all difficulty vanished when we resumed the use of beef-peptonoids.

The question is often asked, "How long can life be supported by rectal feeding?" Experience teaches that, except in cases of malignant disease (always self-limited), there is practically no limit. Dr. Austin Flint reports one case, in which a woman subsisted for *five years*, almost wholly in this way, and during a period of one year and three months her sole nourishment was thus obtained (*Am. Practitioner*, January, 1878). Many other cases might be cited, did space allow. We can only refer to them by giving date, journal, author, etc. The possibility of sustaining life by enemata has been supposed to involve the presence of secretory or assimilant glands in the descending colon. Unless we admit that a *reversal of peristaltic action* is possible, by which nutrient enemata, partially digested by artificial means, are carried into the smaller bowel, it will be found very difficult to account for the success which has followed this mode of nutrition. The permeability of the entire alimentary canal by enemata is an established fact (see "Med. and Surg. Hist. of the War," part ii., p. 836). Enemata have passed through the whole digestive tract, and been ejected by the mouth (*Quebec Med. Journ.*, 1827, ii., p. 201); also Dr. R. Baltry, *Virginia Med. Monthly*, Richmond, 1878, v., p. 531. Of course mere mech-

anical force could not secure this result. It is self-evident that while the injecta may have been carried as far as the cœcum by force alone, the only way in which it is possible to account for a fact so remarkable as the above, is upon the theory of a reversal of the incessant and automatic action of the muscular wall of the small intestines.

It is extremely improbable that assimilation takes place in the lower bowel, save as crystallizable principles may dialyze through the mucous membrane. There is ample authority establishing the fact that only a doubtful opinion is now held as to the existence of solitary glands in the rectum, in any number which is of practical importance. No physiologist would for a moment accept the theory that the down-dragging hemorrhoidal plexus of veins which embraces the rectum can, by any stretch of imagination, be erected into truly absorbent organs, much less organs capable of converting proximate principles into those emulsions which alone can be taken up by the lacteals of the small intestines.

In fine, the lower bowel is essentially an excretory magazine, and should be so regarded in dealing with this whole question. That absorption of excrementitious matter could have been intended, or under any circumstances rendered consistent with health, is wholly illogical.

In this connection I direct attention to the case of a distinguished gentleman whom I am now treating for persistent inability to digest any form of food in the stomach. Four hours after receiving an injection of peptonized beef-broth, he declares that he distinctly recognizes the taste of the peptonoids in the mouth.

The same truth is instanced in two cases of fistulous openings in the transverse colon. In one of them, reported by Voillemier ("Bulletin Soc. Anat.," Paris, 1842, xvii., p. 339), through an artificial anus above the sigmoid flexure, perfectly emulsionized injecta were obtained.

Dr. Thomas J. Gallaher, of Pittsburgh, says (*New York Medical Journal*, 1879): "It is now taught that the albuminous, caseous, and fatty elements of enemata cannot be absorbed by the large intestines *without previous digestion*, and that when these substances are introduced into the rectum unchanged, they are precipitated upon the walls of the bowel, where they undergo fermentation and cause flatulency and pain."

A curious case is reported by Dr. J. H. Beech (*Michigan Medical News*, March 10, 1878), as having occurred in 1859. Sympathetic irritability, due to encephaloid of fundus and body of the uterus, rendered retention of any kind of food impossible. The only injecta used were chicken-broth, coffee and cream, beef-tea, with occasionally milk and eggs. She remarked that coffee and cream relieved the sense of "*famishing thirst*" better than any other injection. As she could not swallow or retain liquids, this fact was of the first importance. It also serves to confirm the doctrine of reversal of peristaltic action.

I subjoin a few cases of my own which illustrate the general statements made:

Case I.—J. D——, aged thirty-eight; cancer of the pylorus. Was unable to retain food of any kind. Great emaciation, thirst, hunger, and distressing insomnia. Ordered 6 ounces freshly made beef extract, with the addition of a teaspoonful of beef peptonoids, thrown into the rectum every four hours. At intervals of eight hours one-half ounce of whiskey was added, and at night twenty minims of McMunns' elix. of opium, in case rest had ready been obtained. It was not necessary a second night. Under this treatment the mor inent symptoms—thirst, sense of hunger, ing, and insomnia—were mitigated in a rem degree. This patient was supported for m three months in comparative comfort, dyi by extension of the local disease to oth organs.

Case II.—Mrs. H. R——, aged about fort tric ulcer. Frequent vomiting, rejecting the food taken. The most bland food tak the stomach produced obstinate nausea an ing. For some months previous to my fi had suffered from persistent constipation. injecta of freshly made beef extract with pe every four hours during the day, with occas ditions of stimulants as required. This t was continued for a period of three month which time she has taken only a small qu water per orem. For the past three week dences of reparation of the local trouble servable, peptonized milk and a tolerabl diet have been given per orem. Case in because reparative processes continued other treatment.

Case III.—Mrs. J. D——, aged nineteen. para. Persistent vomiting from pregnan able to retain either food or drink taken stomach. All the ordinary means used fail lieve the reflex irritability of the stomach emaciation, great general distress, and res followed; symptoms so urgent as to threat result. Abortion was apparently the only be pursued, until I happily thought that enemata of beef extract with peptonoids I able to sustain life and strength until th period of pregnancy was passed. This was d occasional additions of stimulants and ano indicated. Her strength was restored and relieved. After three months she became take beef extract with acid nitro-mur. dil. now in the fifth month of pregnancy, and general condition.

Case IV.—W. H. H——, aged fifty-eig been a generous liver, using wines at his m in moderation. Has had for the past t more or less frequent attacks of gastralgia while the stomach was comparatively em tacks characterized by severe pain and nau evidence of organic disease of either live neys. First treatment was by aconite, carb., magnesiæ sulph. and bitter tonics. relief lasted for a period of several mont cently, however, the same symptoms in a vated form recurred. Total inability to r food or liquid. Great local pain followed tempt to swallow food, and a peculiar featu case was inability to retain pepsin in a Gave 6 to 8 ounces beef extract with pe per rectum three times daily, which had the ate effect of giving rest, ease, and subsiden nausea and vomiting. After four days he able to resume stomachic digestion, beginn a light diet of bouillon, and at present (al weeks after the attack) is able to ride out a beef-steak each morning. I observed also lowing the rectal administration of beef pe his pulse became less frequent, and the reli the symptoms was prompt and complete.

Case V.—Mrs. S——; age about twent primipara; puerperal septicæmia, the sequ

[redacted] the most [redacted] plying artificial [redacted] acquainted. Our [redacted] when I refer to the [redacted] strongly marked in the [redacted] patient. The result of the use [redacted] was that the lower bowel [redacted] count of enemata. [redacted] and the general [redacted] relieved. The [redacted] this form were at first [redacted] and probably for [redacted] decomposition [redacted] each alternate day they were [redacted] in ica. Recently, however, [redacted] preparation of beef peptonate [redacted] Messrs. Reed & Carnrick [redacted] pared by these gentlemen, the value of which in the [redacted] physician and surgeon can scarcely be overestimated, inasmuch as it is always immediately available, not dependent upon refrigeration for integrity of condition, and the results of its use are even more marked and immediate than those of any of the numerous preparations which I have heretofore employed.

W. Joseph Tyson, M.D., F.R.C.S., Parkestone, in *British Medical Journal*, March 5, 1881, says: "To show how little this method of feeding is valued, I quote from Wood's well known treatise on therapeutics (3d ed.): 'The solvent influence of the rectal juices is practically nothing, and formerly the attempt was made to supplement this complete lack of power by the use of soups. It is evident that very little nutriment can be introduced into the system by such a plan; consequently feeding by the rectum has hitherto been a forlorn hope.'" Dr. Tyson adds: "Here, I take it, the author is speaking of unpeptonized injections of food." He then recounts some of his own experience which is so coincident with that already described that I content myself with reference to this very interesting article.

Finally, I deem it a duty to my fellow-men, as well as to the profession, to urge the importance of a careful study of this whole subject. Valuable lives may often be saved, and health and comfort regained, by the means alluded to in the latter part of this article, while alleviation of distress is in a great many cases proved possible by the references given, as well as by my own experience. It is true that in many forms of malignant or senile disease we can only look for a limited prolongation of life without return to health. Yet, even in these extreme cases, who shall deny that it is the stern duty of the physician to use every safe measure which shall secure even one more hour of existence!

The theory is simple, and is amply supported by indubitable reports. My only wonder is (after careful examination of the subject) that so many years have elapsed since ancient experiments without a more general adoption of a plan of nutrition at once safe, easy of administration, and always practically effective.

My thanks are due to Dr. W. C. Tilden for the laborious research required in securing the references to this subject.

THE VOLUNTARY DISLOCATIONS OF A CONTORTIONIST.—Dr. Edmund Owens has furnished (*British Medical Journal*, May 6, 1882) an interesting account of the remarkable feats accomplished by Warren, the American contortionist, whose marvellous facility in effecting dislocations was once described by Dr. F. H. Hamilton. It appears that Warren is now thirty-four years of age, and possesses a most excellent physique, his muscular system having reached a rare grade of development. Being, as a child, subject to spontaneous luxations of the hip, he found himself able to rectify the mal-positions by his own personal exertions. Hence the origin of his efforts in this line. Now he has secured for himself control over certain isolated muscles, which usually are seen to act in concert. The following can thus be contracted individually: the biceps, supinator longus, radial extensors, sartorius, and platysma. But the most astonishing act is undoubtedly the one of which mention has already been made, viz., the dislocation of either hip-joint by personal muscular action. These deformities present all the features seen in Sir Astley Cooper's illustrations, except that the toes of the affected side do not necessarily preserve their classical relations to the opposite foot. Interesting as it would be, it is impossible to study out in detail the order of muscular movements over the course taken by the head of the bone in assuming its false position. But when accomplished, the summit of the great trochanter is at least one and a half inches above Nélaton's line, the cavity of the acetabulum is empty, and the head has travelled upward and backward. Among Warren's other accomplishments, he possesses the power of so contracting the abdominal muscles as to flatten the belly and thus define the aorta through the abdominal walls; or he can produce a phantom tumor by withdrawing the intestinal coils into the grasp of the rectus and oblique muscles. The tumor so produced is dull on percussion, and might even invite exploratory puncture.

anical force could not secure this result. It is self-evident that while the injecta may have been carried as far as the cœcum by force alone, the only way in which it is possible to account for a fact so remarkable as the above, is upon the theory of a reversal of the incessant and automatic action of the muscular wall of the small intestines.

It is extremely improbable that assimilation takes place in the lower bowel, save as crystallizable principles may dialyze through the mucous membrane. There is ample authority establishing the fact that only a doubtful opinion is now held as to the existence of solitary glands in the rectum, in any number which is of practical importance. No physiologist would for a moment accept the theory that the down-dragging hemorrhoidal plexus of veins which embraces the rectum can, by any stretch of imagination, be erected into truly absorbent organs, much less organs capable of converting proximate principles into those emulsions which alone can be taken up by the lacteals of the small intestines.

In fine, the lower bowel is essentially an excretory magazine, and should be so regarded in dealing with this whole question. That absorption of excrementitious matter could have been intended, or under any circumstances rendered consistent with health, is wholly illogical.

In this connection I direct attention to the case of a distinguished gentleman whom I am now treating for persistent inability to digest any form of food in the stomach. Four hours after receiving an injection of peptonized beef-broth, he declares that he distinctly recognizes the taste of the peptonoids in the mouth.

The same truth is instanced in two cases of fistulous openings in the transverse colon. In one of them, reported by Voillemier (" Bulletin Soc. Anat.," Paris, 1842, xvii., p. 339), through an artificial anus above the sigmoid flexure, perfectly emulsionized injecta were obtained.

Dr. Thomas J. Gallaher, of Pittsburgh, says (*New York Medical Journal*, 1879) : " It is now taught that the albuminous, caseous, and fatty elements of enemata cannot be absorbed by the large intestines *without previous digestion*, and that when these substances are introduced into the rectum unchanged, they are precipitated upon the walls of the bowel, where they undergo fermentation and cause flatulency and pain."

A curious case is reported by Dr. J. H. Beech (*Michigan Medical News*, March 10, 1878), as having occurred in 1859. Sympathetic irritability, due to encephaloid of fundus and body of the uterus, rendered retention of any kind of food impossible. The only injecta used were chicken-broth, coffee and cream, beef-tea, with occasionally milk and eggs. She remarked that coffee and cream relieved the sense of "*famishing thirst*" better than any other injection. As she could not swallow or retain liquids, this fact was of the first importance. It also serves to confirm the doctrine of reversal of peristaltic action.

I subjoin a few cases of my own which illustrate the general statements made :

Case I.—J. D——, aged thirty-eight ; cancer of the pylorus. Was unable to retain food of any kind. Great emaciation, thirst, hunger, and distressing insomnia. Ordered 6 ounces freshly made beef extract, with the addition of a teaspoonful of beef peptonoids, thrown into the rectum every four hours. At intervals of eight hours one-half ounce of whiskey was added, and at night twenty minims of McMunns' elix. of opium, in case rest had not already been obtained. It was not necessary after the second night. Under this treatment the more prominent symptoms—thirst, sense of hunger, vomiting, and insomnia—were mitigated in a remarkable degree. This patient was supported for more than three months in comparative comfort, dying then by extension of the local disease to other vital organs.

Case II.—Mrs. H. R——, aged about forty. Gastric ulcer. Frequent vomiting, rejecting most of the food taken. The most bland food taken into the stomach produced obstinate nausea and vomiting. For some months previous to my first visit, had suffered from persistent constipation. Ordered injecta of freshly made beef extract with peptonoids every four hours during the day, with occasional additions of stimulants as required. This treatment was continued for a period of three months, during which time she has taken only a small quantity of water per orem. For the past three weeks, as evidences of reparation of the local trouble were observable, peptonized milk and a tolerably liberal diet have been given per orem. Case interesting because reparative processes continued under no other treatment.

Case III.—Mrs. J. D——, aged nineteen. Primipara. Persistent vomiting from pregnancy. Unable to retain either food or drink taken into the stomach. All the ordinary means used failed to relieve the reflex irritability of the stomach. Rapid emaciation, great general distress, and restlessness followed ; symptoms so urgent as to threaten a fatal result. Abortion was apparently the only course to be pursued, until I happily thought that by using enemata of beef extract with peptonoids I might be able to sustain life and strength until the critical period of pregnancy was passed. This was done, with occasional additions of stimulants and anodynes as indicated. Her strength was restored and distress relieved. After three months she became able to take beef extract with acid nitro-mur. dil. She is now in the fifth month of pregnancy, and in good general condition.

Case IV.—W. H. H——, aged fifty-eight. Has been a generous liver, using wines at his meals, but in moderation. Has had for the past two years more or less frequent attacks of gastralgia, usually while the stomach was comparatively empty. Attacks characterized by severe pain and nausea. No evidence of organic disease of either liver or kidneys. First treatment was by aconite, sodii bicarb., magnesiæ sulph. and bitter tonics. Entire relief lasted for a period of several months. Recently, however, the same symptoms in an aggravated form recurred. Total inability to retain any food or liquid. Great local pain followed any attempt to swallow food, and a peculiar feature of the case was inability to retain pepsin in any form. Gave 6 to 8 ounces beef extract with peptonoids per rectum three times daily, which had the immediate effect of giving rest, ease, and subsidence of the nausea and vomiting. After four days he became able to resume stomachic digestion, beginning with a light diet of bouillon, and at present (about two weeks after the attack) is able to ride out and eat a beef-steak each morning. I observed also that following the rectal administration of beef peptonoids his pulse became less frequent, and the relief of all the symptoms was prompt and complete.

Case V.—Mrs. S—— ; age about twenty-eight ; primipara ; puerperal septicæmia, the sequel of un-

usually long and complicated labor, followed by acute cystitis with purulent discharge. Drs. Johnson Eliot and Robert Reyburn, of this city, were in consultation with me during the labor, the latter frequently visiting her with me subsequently, during the course of the septic fever. This case presented the more prominent and typical expressions of septicæmia, such as frequent rigors, generally more severe in the evening, great heat, extreme pungency of the skin, etc. The temperature ranged from 101.4° to 104°; pulse, 120 to 130; distressing restlessness, and characteristic mental disturbance. The lochia continued normal until the septic condition developed on the eighth day. Pultaceous passages from the bowels generally twice in twenty-four hours, and occasionally attacks of diarrhœa, which readily yielded to ordinary remedies. Tongue red at tip and edges, dry and covered with dark brown fur. Nausea and occasional vomiting. During the first five days of the fever the patient was unable to retain food. Only a little cracked ice was tolerated, even iced champagne being rejected. One tablespoonful of beef peptonoids dissolved in six ounces of moderately warm water, to which 4 drachms of whiskey and 5 grains of quinine, and occasionally 5 to 10 drops of deodorized tinct. opii were added. The quantity of the latter was increased at night to secure rest. These enemata were repeated every four to six hours for a period of four days, when the extreme irritability of the stomach had so far subsided as to enable it to retain the peptonoids and light milk-punches. These were alternated every third hour.

The above outline records the entire nourishment given this patient for eighteen days. The only medication other than that mentioned, was ½ gr. calcium sulphide every four hours, and occasional doses of carbolic acid and lime-water, with the view of sustaining the general antiseptic treatment, which included washing out the bladder twice daily with a solution of biborate of soda.

In a long experience I have never seen a case of this kind as serious as this in which the patient was so well sustained and repair so wonderfully prompt. In my judgment this was entirely due to the temporary relief of the stomach by injecta of peptonoids, and subsequently, as the stomach regained tone, repairing waste by a constant supply of these most assimilable nutrients. The patient is now (thirty-three days after delivery) safely convalescent.

Case VI.—The late President Garfield was some of the time entirely, and all of the time very largely, sustained by rectal feeding from the 14th of August until his death on September 19th. The value of this method of supplying waste in grave disease has never been more strikingly shown than in this instance, because in all probability there never was a patient more closely observed by his medical attendants, and because the quantity and quality of the rectal diet were most carefully regulated, both as to mode and time of administration. During the stage of inflammation of the parotid gland (eight days) this mode of sustenance was entirely relied upon, he being unable to take any food by the mouth and stomach, and only very small quantities of cracked ice and water, which were frequently rejected.

The quantities, carefully measured, were prepared at the dispensary of the Surgeon-General by Hospital Steward W. F. Crusor, U.S.A., in accordance with the following formula After the removal to Elberon, Mrs. Garfield herself prepared it.

War Department, Surgeon-General's Office,
Washington, July 26, 1873.

Circular Orders, No. 6.

The accompanying formula for the preparation of beef extract will be substituted for receipts Nos. 9 and 14 on the "Diet Table for Hospitals," issued from this office February 7, 1873.

By order of the Surgeon-General.

C. H. Crane,
Assistant Surgeon-General, U. S. Army.

"Beef Extract.—*Directions.*—Infuse a third of a pound of fresh beef, finely minced, in 14 ounces of cold soft water, to which a few drops (4 or 5) of muriatic acid and a little salt (from 10 to 18 grains) have been added. After digesting for an hour to an hour and a quarter, strain it through a sieve and wash the residue with 5 ounces of cold water, pressing it to remove all soluble matter. The mixed liquid will contain the whole of the soluble constituents of the meat (albumen, creatine, etc.), and it may be drank cold or slightly warmed. The temperature should not be raised above 100° F., as at the temperature of 113° F. a considerable portion of the albumen, a very important constituent, will be coagulated."

Two ounces of beef extract, 2 drachms of beef peptonoids, and 5 drachms of whiskey were given with scrupulous regularity every four hours, day and night. Occasionally 5 to 15 drops of deodorized tinct. opii were added as an additional nerve stimulant and anodyne, and also to secure retention of the enema. They were usually retained without causing any discomfort on the part of the patient, and, as a rule, once in twenty-four hours a discharge of healthy fæces occurred, generally of such consistence and form as would justify the belief that digestion had taken place in the small intestine. For the first five or six days the yolk of an egg was added to the injections, but in the judgment of the surgeons was the cause of annoying and offensive flatus. This symptom was promptly relieved by discontinuing the egg, and temporarily adding about a drachm of willow charcoal to the enema. Charcoal tablets by the mouth were also occasionally used.

There was a strong desire on the part of the physicians to discontinue the use of the stimulants, but on each occasion when the attempt was made the pulse became more frequent and feeble, so that we were forced to resume their use. Later in the history of the case, after the removal to Elberon, alimentation both by the rectum and the mouth was found to be borne without evidence of peristaltic antagonism.

In my own experience this is rare, one method being usually found more successful when the other was temporarily abandoned.

At this period fresh, defibrinated blood (supplied by my friend Dr. Andrew H. Smith) was, for four days, substituted for the beef peptonoids previously used. It was found, however, that the volume of offensive gases developed, together with the character of the ejecta, rendered a return to the beef extract and peptonoids necessary.

Early in the history of the use of enemata in this case, a firm in New York—Messrs. Reed & Carnrick—sent me a formula for the manufacture of a preparation which they called beef peptonoids, describing minutely their mode of preparing them. This I at once submitted to the council of surgeons, by whom it was approved as affording

the most reliable and effective means of supplying artificial nourishment with which we were acquainted. Our solicitude may be readily imagined when I refer to the evidences of inanition then so strongly marked in the case of our distinguished patient. The result of the use of these preparations was that the lower bowel at once became more tolerant of enemata. No offensive gases were generated, and the general condition of malaise was greatly relieved. The materials so kindly furnished us by this firm were at that time prepared in liquid form, and probably for this reason were liable to undergo decomposition at high temperatures. Therefore on each alternate day they were sent fresh, and packed in ice. Recently, however, I have been using this preparation of beef peptonoids supplied me by Messrs. Reed & Carnrick in powdered form, prepared by these gentlemen, the value of which to the physician and surgeon can scarcely be overestimated, inasmuch as it is always instantly available, not dependent upon refrigeration for integrity of condition, and the results of its use are even more marked and immediate than those of any of the numerous preparations which I have heretofore employed.

W. Joseph Tyson, M.D., F.R.C.S., Folkestone, in *British Medical Journal*, March 25, 1882, says: "To show how little this method of feeding is valued, I quote from Wood's well known treatise on therapeutics (2d ed.): 'The solvent influence of the rectal juices is practically nothing, and formerly the attempt was made to supplement this complete lack of power by the use of soups. It is evident that very little nutriment can be introduced into the system by such a plan; consequently feeding by the rectum has hitherto been a forlorn hope.'" Dr. Tyson adds: "Here, I take it, the author is speaking of *unpeptonized* injections of food." He then recounts some of his own experience which is so coincident with that already described that I content myself with reference to this very interesting article.

Finally, I deem it a duty to my fellow-men, as well as to the profession, to urge the importance of a careful study of this whole subject. Valuable lives may often be saved, and health and comfort regained, by the means alluded to in the latter part of this article, while alleviation of distress is in a great many cases proved possible by the references given, as well as by my own experience. It is true that in many forms of malignant or senile disease we can only look for a limited prolongation of life, without return to health. Yet, even in these extreme cases, who shall deny that it is the stern duty of the physician to use every safe measure which shall secure even one more hour of existence?

The theory is simple, and is amply supported by indubitable reports. My only wonder is (after careful examination of the subject) that so many years have elapsed since ancient experiments without a more general adoption of a plan of nutrition at once safe, easy of administration, and always practically effective.

My thanks are due to Dr. W. C. Tilden for the laborious research required in securing the references to this subject.

THE VOLUNTARY DISLOCATIONS OF A CONTORTIONIST.—Dr. Edmund Owens has furnished (*British Medical Journal*, May 6, 1882) an interesting account of the remarkable feats accomplished by Warren, the American contortionist, whose marvellous facility in effecting dislocations was once described by Dr. F. H. Hamilton. It appears that Warren is now thirty-four years of age, and possesses a most excellent physique, his muscular system having reached a rare grade of development. Being, as a child, subject to spontaneous luxations of the hip, he found himself able to rectify the mal-positions by his own personal exertions. Hence the origin of his efforts in this line. Now he has secured for himself control over certain isolated muscles, which usually are seen to act in concert. The following can thus be contracted individually: the biceps, supinator longus, radial extensors, sartorius, and platysma. But the most astonishing act is undoubtedly the one of which mention has already been made, viz., the dislocation of either hip-joint by personal muscular action. These deformities present all the features seen in Sir Astley Cooper's illustrations, except that the toes of the affected side do not necessarily preserve their classical relations to the opposite foot. Interesting as it would be, it is impossible to study out in detail the order of muscular movements over the course taken by the head of the bone in assuming its false position. But when accomplished, the summit of the great trochanter is at least one and a half inches above Nélaton's line, the cavity of the acetabulum is empty, and the head has travelled upward and backward. Among Warren's other accomplishments, he possesses the power of so contracting the abdominal muscles as to flatten the belly and thus define the aorta through the abdominal walls; or he can produce a phantom tumor by withdrawing the intestinal coils into the grasp of the rectus and oblique muscles. The tumor so produced is dull on percussion, and might even invite exploratory puncture.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 15, 1882.

IODOFORM AND PHTHISIS.

It is probably not possible for madness to ally itself to an entire body of learned men. If it were, we should say that our German brethren were suffering from iodoform monomania. Iodoform is talked of in every medical society, and heads alternate articles in all the medical journals. The insanity of iodoform is quite as apparent as the primäre verrücktheit of Guiteau, but affects the mass instead of the individual.

Iodoform is not only claimed to furnish the ideal surgical dressing, but we every day learn of new external and internal uses for it. Its value in eye, ear, throat, and uterine troubles has long been known, but is now enthusiastically magnified. We find also the iodoform treatment of syphilis competing with that by mercury. It cures diphtheria and gastric ulcer; it is, says Moleschott, a most efficient help in diabetes mellitus.

Very recently Dr. B. Küssner, of Halle, has asserted that iodoform is most helpful and even curative in tuberculosis of the larynx and lungs. Some time ago Aschenbrandt, of Wurzburg, found in experimenting upon cats, that the inhalation of iodoform caused pneumonia and death in these animals. He advised against its use, therefore, in phthisical diseases in man. Küssner, however, reasoned from another standpoint. In all the discussions and disputes over iodoform, one point is uniformly conceded—the drug has an influence, almost specific, over tuberculous swellings and ulcerations. Why should it not, therefore, have an equally good effect upon tuberculosis of internal organs? Küssner, after some trials, found that iodoform inhalations had not the irritating effect upon human lungs which Aschenbrandt predicted. It excited no cough, and was even given to a patient who was subject to attacks of hæmoptysis without harm. Küssner used the drug first in tuberculosis of the larynx. The efficacy of it here is already well known, and nothing especially new is given by our author. His method was to blow iodoform into the larynx once a day. In addition, the patient was made to inhale three or four times daily a solution of iodoform composed as follows: About ʒiss. of a ten per cent. alcoholic solution of iodoform is put in an inhaling apparatus holding an ounce. The apparatus is then filled with water, by which a milky emulsion is produced. The mixture must be prepared fresh each time. The success following this treatment is reported as very great.

In the treatment of pulmonary tuberculosis more difficulty was encountered. In order to get the specific effect of iodoform, the drug needs to be brought into actual contact with the diseased surface. This it is not possible to do by any measure at present known.

The nearest approach to it is by the use of inhalations long continued. These were used by Dr. Küssner. He found that in most cases they produced a diminution in cough and expectoration, with subsidence of fever. The actual permanent good he had not yet been able to determine. The inhalations, he states, must be kept up for months, and this, we are further told, can be done without producing toxic symptoms. The author expresses the belief that by his new method many cases of pulmonary phthisis can be cured.

If so, the present apotheosis of iodoform will be justified. We fear, however, that many persons will prefer phthisis to constantly inhaling iodoform, even if that drug proves of decided value.

MEDICAL JUBILEES.

We intend no disrespect in saying that there are two classes, the medical German and the spiritual African, who look forward with a special definiteness to crowning their life with a jubilee. To the African the "kingdom's comin'" at a rather vague time, varying with the religious illumination of the individual. With the German doctor a jubilee comes on the twenty-fifth or fiftieth year of his doctorate, or perhaps when he has reached two score and ten and is ready to retire from his professional chair.

We are led to comment on the above facts by the frequent occurrence of medical jubilees among our German brethren of late. Virchow, Artl, Bischoff, Henle, Botkin, and others have all had anniversary honors paid to them. Even the medical journals share in this jubilant custom, and the *Allgemeine Medicinische Central-Zeitung*, a Berlin bi-weekly, not long ago celebrated the completion of its twenty-fifth year and fiftieth volume.

The spirit prevailing in the profession which enables the medical jubilee to be so frequently and heartily celebrated is certainly a good one. No one in this country thinks of undertaking such affairs

except in the rarest instances. Can it be that when a medical man gets old his juniors are more anxious to supplant than to honor him?

There are some features in our medical system very different from those in Germany. This may have something to do with the feeling prevailing toward medical seniors. In Germany rational medicine is in the hands of professors, assistants, docents, etc. Those who have anything to write or to say have, as a rule, some official position. The younger men have been pupils of the older, and old and young generally have, in consequence, mutual kindly feelings. When the master has reached his semi-centennial, he has many pupils anxious to do him honor.

It will not be possible for such arrangements to exist here, at least for many years. But there might be cultivated a more cordial respect and sympathy for the Nestors in the profession.

THE QUARREL OVER THE AUTOPSY.

THE quarrel over the matter of the autopsy upon Guiteau adds another unpleasant chapter to a history already full of humiliations to the medical profession. The point at issue was petty enough, and in no way deserved the publicity it has received. Dr. Lamb, as it appears to us, was justified in considering that the two gentlemen who especially assisted at the autopsy were not necessarily associated in making up the report. He was, we believe, actuated solely by a desire to secure and publish an entirely fair report. At the most it can only be said that it might have been more generous if he had made his report contain some acknowledgments of help given him by other gentlemen present.

But the legitimate field for medical criticism is the mode in which the autopsy was conducted and the character of the official report itself as a scientific document. A little examination of the notes upon the autopsy, published in THE RECORD last week, will show that the means for a thorough study of the brain were absent. This occurred apparently quite as much from a lack of knowledge as to what was needed as from want of opportunity. The defects of detail in the autopsy need not be recited here.

As regards the so-called official report, the description of the fissures, convolutions, and contours, undoubtedly the most important part, is most meagre and appears to contain a number of errors. There seemed to have been an inability to use intelligently, as well as to acknowledge courteously, the help given here.

But the subject is not an agreeable one and we do not care to dwell upon it further. Dr. Lamb is an excellent and fair-minded gentleman, who has simply been unconscious of his incompetency to conduct an important autopsy involving a study of the brain. We trust that his misapprehension will now be removed.

THE ARMY RETIREMENT BILL.

BY the retirement clause of the last Army Appropriation bill, the following medical officers were retired, having reached the age of sixty-four years, viz.: Surgeon-General J. K. Barnes, Colonels J. M. Cuyler, and W. S. King, and Lieutenant-Colonel James Simons. Thus has been inaugurated a new rule, which cannot but be of benefit to the whole army, and particularly to the Medical Department, Major Brown, for instance, having been stationary in the rank of major for twenty-one years. Promotion will now flow apace, as the rule adopted will limit the term of service of every officer. No one will say that the officers now retired are beyond further usefulness. They retire to inaugurate the rule, and the sacrifice they are called upon to make for the good of the whole army, of retiring before disability, will be accounted not the least among the acts for which they will be remembered.

These officers were already veterans of the Mexican War, in which Cuyler gained great reputation, and Simons was wounded when the War of the Rebellion broke out. King was the medical director of the first Bull Run, and Barnes and Cuyler became medical inspectors general. Cuyler is one of the most popular surgeons in the army—is respected, loved, and reverenced, above all. Barnes, as Surgeon-General, has had a greater influence on the fortunes of the medical corps than any of his predecessors. He has raised its morale by improving its personnel—the incompetent and black sheep have been excluded, and the vacancies filled by men of such excellence, that the corps to-day stands without a rival. Under the direction of Barnes the splendid "Medical and Surgical History of the Rebellion" has been published, a great medical library has been completed, the most extensive museum of the pathological products of war established, besides the ordinary routine duties, which have pressed not lightly at times. In retiring, Barnes can certainly look back with pleasure on the valuable work he has accomplished.

INSANITY AND DIVORCE.

A DISCUSSION on the question of insanity as a ground of divorce has recently taken place before the Academy of Medicine of Paris, and has excited considerable attention. The only prominent member who advocated that "insanity in certain determined cases should be considered a ground of divorce," was M. Luys. He presented his case very strongly, however, and he is undoubtedly correct in the position which he takes.

The state of the laws in this country regarding the subject in question is somewhat different from that in France, but the difference consists chiefly in rather more lax administration of a similar code. An American authority says: "Insanity occurring after marriage, with or without some predisposition, is, of course, insufficient to invalidate the ceremony,

and, though a misfortune which beclouds many a long conjugal union, is rarely permitted to become a legal ground of divorce, notwithstanding the strong social pressure sometimes exerted to have it added to the list." In Iowa and Kansas not even cruel treatment by one of the parties while insane is allowed as cause.

The only exceptions made are where insanity is brought on by intemperance, or is the result of a concealed hereditary taint. In these cases it is sometimes allowed. Of course, insanity or idiocy existing at the time of the marriage ceremony nullifies the contract.

The arguments used by those who would adhere to these old standards are partly scientific and partly sentimental. Thus it is said on the one hand that it is impossible to make an absolute prognosis regarding the patient's disease. He or she may get well. Then it is said, also, that insanity is only a disease; that the sufferer from it should not be divorced any more than if she had consumption or cancer. It is simply a misfortune, to be borne patiently.

That these are shallow arguments is apparent. The chances of recovery in most forms of insanity after four or five years are practically none. Yet the chances of the patient's living fifteen or twenty years are very great. The man or wife is, therefore, condemned absolutely to a single life. A divorce would free the sane without injuring the insane.

M. Luys, in dwelling upon the sentimental objections to his views, gave some practical facts of which all must admit the truth who are acquainted with asylums. He says that at first the husband or wife who is shut up in an asylum is very frequently visited. Before long, however, the visits become less numerous. In a few years, or sooner, the interest and the visits become perfunctory. It is hard to love a lunatic.

It would be a step in our social progress if the laws provided that in certain forms of insanity from which the party has suffered for (as Luys suggests) four years in man and five in woman, be allowed as a ground of divorce; provided, of course, that a certain provision for the support of the *aliéné* be made.

The only serious objection to such a change is in the practical difficulties which might occur in carrying out such a law and in preventing any abuses developing from it. This, however, is for the lawyer and not the scientist to consider.

An Effort to get Prof. Billroth at Berlin is said to be on foot. Prof. Langenbeck will soon retire from the Surgical Chair at that city. He desires to see his place filled by the one whom he considers his most brilliant pupil. Prof. Billroth is therefore selected. It is very doubtful, however, that any such change can be made.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 12, 1882.

Dr. Edward C. Seguin, President, in the Chair.

Dr. W. M. Carpenter presented a specimen in behalf of a candidate.

Dr. W. R. Birdsall, from the Committee on Microscopy, reported that the tumor presented by Dr. Robert Newman at the Stated Meeting held February 22, 1882 (see Medical Record, vol. xxi., p. 358), consisted simply of inflammatory tissue. No true glandular structure was found, and nothing that suggested the existence of malignant disease.

Dr. N. Bozeman presented a specimen of

CYSTIC SARCOMA OF THE MESENTERY AND OMENTUM,

accompanied by the following history:

The patient, a woman forty-six years of age, and a resident of Chicago, consulted him in February last, on account of an abdominal tumor which had existed, so far as she knew, for about a year. She was of medium height and stoutly built. She had enjoyed good health up to 1872, when she nursed her mother through a long sickness that necessitated standing or sitting most of the time, and this labor was followed by amenorrhœa that lasted for four months, when menstruation reappeared and continued at intervals of two weeks for several months; but it finally regulated itself, and she had good health until April, 1875. At that period she noticed, for the first time, an enlargement in the left side, which, in 1876, had attained considerable size, and was believed to be ovarian in character. Her attending physician tapped it and drew off thirteen ounces of light-colored fluid, and her general health afterward remained very good for eight or nine months, when evidence of refilling of the cyst was developed, and she then consulted a surgeon in Massachusetts. On account of some obscurity in diagnosis, he decided not to operate, and she then came to New York, when she was examined by one of Dr. Bozeman's colleagues in 1878; the tumor diagnosticated to be ovarian; ovariotomy performed, and the patient discharged cured. The patient remained apparently well until August, 1879, when she began to suffer from exhaustion due to over-work, and about a year afterward (1880) she discovered a projection just below the umbilicus, in the line of the former operation. This, however, gave her but little inconvenience at first, but was evidently a hernial tumor. About a year subsequently (1881) an enlargement was noticed to the left of the projecting portion below the umbilicus, and she consulted a surgeon who recognized the hernial tumor, and also expressed the opinion that the tumor to the left of it was ovarian.

On admission into the Woman's Hospital, February 20, 1882, the patient seemed to be in good health, and suffered no special inconvenience except that which was due to the existence of the large protrusion upon the abdomen. She was put upon a course of preparatory treatment for ovariotomy, consisting in the administration of 15 grains of salicin three times daily for two or three weeks; for four or five days immediately preceding the operation she had baths with inunctions with vaseline, and the night before 15 grains of quinine, and the bowels

emptied. Three hours before the operation she received 15 grains of quinine with 1 grain of opium, and went upon the table in good condition and took ether remarkably well. The hernial protrusion gave a peculiar emphysematous crackling sensation, and it was believed to be composed of coils of intestine and fluid, and also it was thought that adhesions existed between the protruding mass and the edges of the opening, which was situated between the recti muscles and was large enough to admit a man's fist. In view of the complication, Dr. Bozeman made an incision through the abdominal wall commencing to the left of the umbilicus, with the view to exploring from above downwards, to determine the condition of the hernia and the borders of the opening. After the incision was made, about two inches long, he was able to satisfy himself that there were no adhesions between the hernial sac and the borders of the opening, and he then extended the incision into the line of the original incision and carried it down to the lower angle. This brought into view the abdominal contents. The hernial protrusion was composed solely of a large cyst projecting forward and upon the right side of the main tumor. The large tumor was found to be very firmly fixed, and in order to ascertain its outline he removed the omentum, and then tapped it and drew off a gallon of fluid, the first being of a light yellow color, then came clear fluid, and this was followed by fluid having the color of claret. He was then able to explore, and found the uterus and remaining ovary in a normal condition. On examining the body of the tumor, it was found to be attached to the mesentery mainly. The adhesions were quite firm but they were broken up and the entire mass was enucleated and removed without hemorrhage. No vessels were ligated. Upon the omentum was a cyst, about the size of a hen's egg, extensively attached to the large tumor, and containing fluid of the same character. Upon the peritonæum, just above the bladder, were two other tumors, solid bloody tumors, easily broken up with the fingers, but they could not be scraped from the peritonæum. From these there was considerable hemorrhage and it was necessary to use the actual cautery to control it. The peritoneal cavity was thoroughly cleansed, and an operation for the radical cure of the ventral hernia was then performed, by excising, upon each side of the original incision, integument around the entire extent of the opening, so as to reach edges which were sufficiently thick to insure union firm enough to prevent recurrence of the difficulty. The wound was then closed in the usual manner with carbolized silk sutures, and a good line of union was obtained. The after treatment consisted in the use of quinine, opium, and the administration of beef juice by the rectum. The wound progressed favorably, but there was nausea and vomiting almost from the beginning, and it continued for forty-eight hours. Her pulse, however, remained below 100 for three days, and the temperature varied from 100° to 100¼° F. On the third day the vomiting had ceased, but the temperature had commenced to rise, and it continued to go up until on the sixth day it had reached 107° F., the pulse 126, and she died of peritonitis.

The tumor was composed of solid matter and cysts, and the large cyst was the one which projected through the opening in the abdominal walls. The solid portion had its attachment to the mesentery. The following is the report of the pathologist, Dr. W. H. Welch:

"The tumor is composed chiefly of cysts, but it contains some solid parts. The external surface of the tumor is in many places smooth and glistening, in other places there are attached bands of fibrous tissues and of adipose tissue, which represent old adhesions. Upon the external surface are unmistakable evidences that some of the cysts have ruptured into the peritoneal cavity. There are, namely, bands and ridges which represent the shrunken walls of ruptured cysts, and which are identical in appearance with similar structures on the inner surface of the cysts. Moreover the external wall of some of the cysts is extremely attenuated, as if about ready to burst.

"Upon sections the tumor is found to be composed of a large number of cysts, some no larger than a pea, others the size of an orange and even larger. The partitions between the cysts varied considerably in thickness, some being one or two centimeters in thickness, others being not more than a millimeter in thickness and film-like. In places there are evidences that the larger cysts are formed by coalescence of smaller ones. It is not possible to dissect the walls of the cysts into a fibrous and a mucous layer, as is the case with ovarian cysts. The thicker walls can be laminated into planes of fibrous tissue, the thinner walls cannot be laminated. There are places where masses of solid tissue are present as large as a hen's egg. This tissue is of a soft consistence and uniform grayish color.

"Upon microscopical examination the solid masses are found to consist almost wholly of spindle and round cells, without any regularity in the arrangement of the cells. These parts therefore are sarcomatous in structure. The inner surface of the cysts is devoid of any epithelial lining, although as a rule it is smooth. Only round and spindle cells can be scraped from its surface. The partitions between the cysts consists chiefly of fibrous tissue, containing blood-vessels and large lymph-spaces. The outer surface of the tumor is covered in smooth places by a layer of endothelial cells.

"The fluid in the cysts is thin and blood-stained, in some cysts yellow, in most claret-colored or brownish. In none of the cysts is any viscid fluid. The specific gravity of the fluid is 1018, the reaction feebly alkaline. Serum albumen is abundantly present, likewise a small quantity of paralbumin. The fluid is possessed of a feeble power of spontaneous coagulability. The microscopical examination of the fluid shows an abundance of normal and of shrunken red-blood corpuscles, also white-blood corpuscles, fat-granule bodies, some spindle-cells, and free granular material; no epithelium.

"The relations of the pedicle cannot be clearly defined.

"Probable diagnosis, *Cystic fibrosarcoma*."

TUMOR OF THE STOMACH.

DR. MESSENGER presented the stomach, removed from the body of a physician, seventy years of age, who began to feel that his health was failing about two years ago, when he had loss of appetite, flesh, and strength, and suffered from indigestion. Nothing very remarkable presented itself until December, 1880, when he first noticed a lump in the left hypochondrium. Having lived considerable of his lifetime in a malarial region, he at first thought it might be some trouble with his spleen, as well as his liver, which he seemed to regard as certainly diseased, functionally at least. The tumor was not painful, and only a slight uneasiness was produced by pressure. He was seen by several of his medi-

cal brethren, all of whom were of the opinion that the disease was malignant and situated in the stomach. For several months before death he vomited a greenish, slimy, more or less frothy material; and for three or four weeks immediately preceding the fatal termination, vomited coffee-ground material. He suffered from pain but little, and died an almost painless death. At the autopsy the liver was nearly normal, and the spleen was somewhat smaller than normal.

The stomach contained a tumor of considerable size. The specimen was referred to the Committee on Microscopy.

Dr. Messenger also presented a hard

TUMOR REMOVED FROM THE BREAST

of a woman about six months ago. It had given the patient considerable pain. Union of the wound took place promptly, and thus far there had been no evidence of recurrence. The specimen was referred to the Committee on Microscopy.

Dr. Sell said that he saw the patient from whose body Dr. Messenger's first specimen was removed, and while there was well-marked cachexia and tumor, the absence of pain was the notable feature, and the absence of vomiting of chocolate-colored material until a few weeks before death.

By way of comparison, Dr. Sell referred to a case in which several eminent physicians in the city had diagnosticated cancer of the stomach, but which made an apparent recovery at least, several times. Having succeeded in establishing these recoveries, he finally diagnosticated ulcers of the stomach, and the autopsy revealed, impaction of fæces, slight hardening of the pylorus, dilatation of the stomach, numerous cicatrices in the gastric mucous membrane, ulcerations of the stomach and of the œsophagus just before entering the stomach, and also ulcers in the duodenum.

Dr. E. L. Partridge presented a placenta, funis, and the remains of membranes which illustrated

PLACENTAL APOPLEXY AND SHORTENED FUNIS.

The patient was twenty years of age, single, and confined at the New York Infant Asylum, under the care of Dr. Parker, resident physician. Her last menstruation was in August, 1881. She felt quickening about the first of January, 1882. Her labor took place April 7, 1882.

Past health good, no syphilis as far as can be known. No history of injury, and during five weeks preceding labor was in hospital under observation, and no injury possible without cognizance of the resident physician. Patient not very bright, felt well up to occurrence of labor, supposing she felt life till that time.

The second stage of labor lasted thirty minutes, the third stage ten minutes. Pains normal. No recession of head during the second stage in intervals of contraction. The cord was not wound upon a limb or about the neck.

The child weighed two and a half pounds, and had the appearance of having been dead two weeks or more. The liquor amnii was of a dark coffee color. The placenta was of the size corresponding with end of the seventh month of gestation.

On its maternal surface was a depression two and a half inches in diameter, and an inch in depth, occupied by a clot of considerable consistency and tarry color. The edges of the cavity were smooth, and the placental tissue immediately adjacent was more dense than usual. On the fœtal side of the placenta almost directly opposite the clot was the insertion of the funis. The funis measured ten inches only.

The case illustrated one of the dangers attending short funis, viz., accidental hemorrhage and consequent death of the fœtus.

The cord being short, some sudden, violent motion of child produced dragging upon it, sufficient to detach the placenta and allow hemorrhage, in this case opposite the insertion of the cord. The condition of the fœtus indicated that its death took place quite a time previous to the labor.

The peculiar color of the clot, very dark, and its failure to be very firm and hard, would indicate that the child died at the time of the hemorrhage. If it had retained its life for a time, the utero-placental circulation continuing, the coloring matter and fluid constituents would have been removed from the coagulum, as can be demonstrated after those cases of accidental hemorrhage, when the child is born alive, and firm and more or less colorless clots escape with the placenta.

The coagulum resembled, in this case, that which would be found in an hæmatocele.

The specimen was referred to the Committee on Microscopy.

FUNGOUS ARTHRITIS—ARTHROTOMY AND SUBSEQUENT AMPUTATION.

Dr. C. K. Briddon presented a specimen with the following history. Mary Z——, twenty years of age, born in Ireland, single, and a domestic, was admitted to the Presbyterian Hospital January 20, 1882. The following notes of the case were furnished by Dr. H. A. Mandeville, house surgeon. The patient's family history was good. She had enjoyed good health, although always delicate, and had had most of the diseases of childhood. In February, 1881, she had a severe fall, striking on her left knee, to which she at first paid no attention, but subsequently it became swollen and tender on pressure, and in March of the same year she entered a hospital, where she was treated until October, when she was much improved. Last December she had another acute attack of inflammation in the joint, when an abscess formed on the inner side of the left knee, which opened spontaneously, giving vent to a thick, yellowish discharge.

On admission the patient was strumous and anæmic, and the knee-joint fixed and flexed. There were three small unhealthy ulcerating surfaces around the left leg, about two inches below the joint. At the bottom of each a small sinus led toward the joint. No dead bone was detected. Joint enlarged and somewhat tender. Evidences of old operation over head of tibia on the other leg.

Treatment consisted of rest, extra diet, tincture of iron, and cod-liver oil.

Under these her general condition improved somewhat, though the sinuses showed very little tendency to close. Within the last few days a scanty exudation of a material resembling synovial fluid appeared on the sores at each dressing. She was carefully probed, but no connection with the joint could be made out.

February 9th.—Chill, with considerable constitutional disturbance. Temperature, 104¼° F.; pulse, 124. Swelling increased. Throbbing pain in the joint, which was excessively tender. Ice to joint.

February 14th.—General condition running down rapidly. Joint symptoms all aggravated; insomnia and great complaint of pain. Temperature, 103° to

105° F.; pulse, 112 to 132. Operation by Dr. Briddon. Ether was given, and an incision six inches long made on either side of joint, evacuating a large quantity of pus. As the capsule of the joint was distended, it was aspirated, and pus detected. Free incisions were then carried through the capsule on either side, evacuating a considerable quantity of curdy pus. The synovial membrane was covered with granulation material. Three drainage-tubes were inserted clear through joint and syringed freely with acid carbol. dil. (1—40), carbolized gauze dressings were applied, and the limb put in a fenestrated immovable apparatus.

March 1st.—The patient's general condition improved somewhat after the operation. The wound was dressed every day with ℞. iodoform, ʒ i.; bals. Peru, ʒ iii.; vaseline, ʒ i. M. The cavity soon filled up with exuberant, pale, flabby granulations, and today the drainage-tubes were removed. Each dressing caused her extreme pain, and no adequate amount of pressure could be used. The granulating surfaces were covered with unhealthy gelatinous material. Iodoform dusted all over was substituted for the ointment before used, and the dressings were not removed for four to six days. After this, together with disturbance caused by fever and sweating, she began to suffer from occasional excessive nausea. Her temperature ever since the operation has ranged from 103° to 105° F., and pulse rapid and weak. Her general condition rapidly became poorer. Cough appeared, with sweating profusely at night. All symptoms but very little controlled by any treatment. Locally there was very little improvement, and the joint caused her excessive pain, and after each dressing her condition was extremely critical.

April 10th.—Bad bed-sores have appeared during the past few weeks, despite most careful care and water bed. There was now evidently no means of saving her life save by amputation, which was advised and accepted by the patient. Ether was given; and Dr. Briddon amputated the thigh at the middle with the lower third, by modified circular method. Very little blood was lost. The ends of the drainage-tube were left external to the dressings, which consisted of absorbent cotton, over the whole of the stump, and snug roller.

Condition of joint.—There was an abscess behind the head of the tibia communicating with the joint. The synovial membrane was in a condition of pulpy degeneration. The outer articular cartilages and the cartilages of incrustation were gone at several points on both joint-surfaces. The dense lamellæ of bone that underlies the cartilage were absorbed, exposing the cancellous structure.

Dr. Gibney asked concerning the condition of the patient's lungs at the time of the amputation.

Dr. Briddon said there was no evidence of organic disease, and since the operation the pulmonary symptoms had disappeared.

Dr. Gibney referred to a case, recently under his observation, in which he had occasion to remove the foot post-mortem and found nearly complete loss of the lower part of the tibia, and about one-third of the astragalus had been destroyed by caries. The boy was about fourteen years of age, had hectic fever, which he attributed to the disease of the ankle-joint, and did not examine the lungs. He supposed that the patient died of caries of the ankle-joint, but at the autopsy a large cavity was found in the right lung, and two-thirds of the left lung contained numerous small abscesses with marked increase of fibrous tissue, so that the only breathing space remaining was very small, and in making up the history of the case he found a marked tuberculous tendency.

He regarded it as not uncommon to have phthisis developed in children with caries of joints, even after the joint disease seems to be cured.

Dr. Briddon did not wish to be regarded as holding the opinion that it was proper to amputate for suppurating joint disease in patients with serious lung disease. In the beginning amputation might save life; but in advanced cases of pulmonary disease with caries of a joint, amputation might hasten the fatal result.

Dr. Peabody asked concerning the result of amputation through such a diseased joint, provided that skin enough could be obtained to make the flaps.

Dr. Briddon said that it was always desirable to operate as low as possible. Amputation through the joint, however, required large flaps, sometimes impossible to obtain. In his case the sinuses had degenerated into very large open sores covered with exuberant granulations, and the surrounding skin was undermined. But it is not necessary to sacrifice much of the bone to obtain readily flaps of sufficient size, and the operation he recommended was Carden's, removing a thin slice of bone embracing the articular surface of the femur, opening into the cancellous structure, but not into the medullary cavity. Of course, every inch of bone saved was important with reference to the subsequent use of an artificial limb.

SARCOMA OF THE OVARY.

Dr. George L. Peabody presented an ovary removed from the body of a woman, forty-two years of age, who died with symptoms accompanying chronic diffuse nephritis and amyloid infiltration of the Malpighian bodies and other blood vessels. The ovary was about the size of a hen's egg, and a firm, solid mass. The uterus had four myomata. The ovary was made up of a fibrous stroma, in the meshes of which were imbedded, without special arrangement, a large number of small round cells, a few spindle cells, and in the midst of these were large blood-vessels with thin walls. There was also some colloid material in which were lymphoi cells. There were no secondary deposits in any of the other organs. There was no history of symptoms referable to the ovary. The mucous membrane of the alimentary canal also showed amyloid degeneration.

ANEURISM OF THE RIGHT MIDDLE CEREBRAL ARTERY.

Dr. W. M. Carpenter presented a specimen which he removed from the body of a man who was found dead and brought to the Morgue. The stomach contained partially digested food. The aorta was atheromatous. The heart, lungs, and abdominal organs were normal. Profuse hemorrhage had occurred in the cranial cavity, and on examining the base of the brain it was found that the right middle cerebral artery had an aneurismal dilatation in its main trunk, seven-eighths of an inch long and half an inch in its greatest diameter. The sac had ruptured in its attached surface, where the tissues—when the sac was distended with air from the blow-pipe—were as transparent as is the arachnoid. The other arteries, at the base of the brain, were more or less atheromatous.

The President referred to a case which he saw

with Dr. Emerson, and which afforded a most remarkable example of sudden death. The man was reported by his wife and mother to have died almost in a moment, after having some obscure symptoms.

The autopsy revealed aneurism of the basilar artery and intermeningial hemorrhage.

Dr. Tauszky presented a specimen which illustrated

ULCERATIVE SYPHILITIC LARYNGITIS.

It was obtained by the favor of Dr. M. J. B. Messemer, deputy coroner, and was removed from the body of a man who was an inmate of the Colored Home, and committed suicide. There was a history of syphilis dating back to 1878. The man suffered greatly from dyspnœa, and arrangements had been made to perform tracheotomy. There was ulceration of the thyroid cartilage, necrosis of the lower part of the epiglottis, a loss of substance, and the left vocal cord was ulcerated. During the last two weeks of life there was great difficulty of deglutition.

Dr. Tauszky also presented a specimen of

UTERINE POLYPUS,

removed from a woman thirty-nine years of age, who had given birth to six children. The case had been diagnosticated to to be one of carcinoma; but dilatation of the cervical canal revealed the little tumor, half an inch in diameter and an inch and one-half long, which was readily removed and the patient cured.

Dr. Briddon believed that in the earlier stages of syphilitic laryngitis it was good treatment to perform tracheotomy and set the larynx at rest. Doubtless a prompt operation in the case Dr. Tauszky had mentioned would have saved the man's life. He then referred to a case in which the man was dying of apnœa from ulcerative syphilitic laryngitis, when he performed tracheotomy; the breathing after a little time became unembarrassed, and the patient recovered so as to be able to go about, but was never able to dispense with the tube. On several occasions Dr. Briddon was obliged to remove hard lumps of mucus from the trachea, and finally he made a free incision and removed the thyroid cartilage almost entirely, and it was found to have undergone calcification, and subsequently necrosis. The man died at the end of two or three weeks of exhaustion due to suppuration.

MALFORMATION OF THE HEART.

Dr. J. Lewis Smith presented a specimen with the following history: Some months ago he was asked at the New York Infant Asylum to examine a child that had become cyanotic. Nothing unusual was noticed concerning the infant until it was three weeks old. It was born of a mulatto woman, twenty years of age, and a primipara. The lividity was very marked, and it seemed evident that the child would not live very long. At various examinations, a loud systolic murmur was heard over any part of the chest, even laterally. Death occurred at the age of five months and twenty days, and was somewhat sudden. The development of the child was fair, it being wet-nursed by its mother. At the autopsy the chest was found rounded and bulging, corresponding with the lower third of the sternum. The lungs had probably never been fully inflated—the respiratory murmurs during life had been feeble, and were almost in the condition of semi-atelectasis.

The heart was nearly globular, its centre a little to the right of the median line. On removing it, a careful examination was made by Dr. Dawson, who found that the interauricular septum was nearly absent, leaving one cavity instead of two; and there was also a large opening in the interventricular septum. There did not seem to be constriction of the pulmonary artery sufficient to interfere with the circulation. There was a transposition of the aorta and pulmonary artery: the pulmonary vessel arising from the left ventricle, and the aorta arising from the right ventricle. At the arch they were in nearly the normal relation to each other.

The ductus arteriosus was probably enlarged.

The Society then went into executive session.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, April 25, 1882.

Dr. T. M. Markoe, President, in the Chair.

Dr. R. F. Weir read a paper

ON SOME RECENT METHODS OF TREATING HYDROCELE [see page 57].

Dr. Briddon remarked, concerning injections of iodine, that he had had considerable experience in that method and with only a very few failures. But he always allowed the iodine solution to remain in the sac, and he believed that that was one of the reasons, perhaps the chief, why the method had been so successful in his hands. He commonly used a drachm or a drachm and a half of Gugol's solution. He had performed Volkmann's operation in some half dozen cases, and had found it very difficult to keep the operation wound antiseptic with dressings.

Dr. A. C. Post referred to one case in which Volkmann's operation was performed by one of his colleagues, and it was followed by an amount of inflammatory swelling and induration he had never seen from the use of iodine injections, and it remained for several weeks.

Dr. L. A. Stimson referred to one case in which he used a solution of chloride of zinc, recently recommended for injecting the sac. The patient was a delicate boy, seventeen years of age. He did not dare to make the iodine injection from fear of excessive reaction. He first tapped the hydrocele two or three times, removing from 100 to 125 c.c. of clear serum, and then injected one drachm of a five per cent. watery solution of chloride of zinc through a hypodermic needle, immediately after removing about a drachm of the fluid. The injection caused no pain, but, almost immediately, the remaining serum coagulated. He heard nothing from the patient until the fifth day, when he returned and gave the following history. In the evening of the day on which the operation was performed he became nauseated, the scrotum became swollen and tender, also the penis. The nausea remained through the night and the next day, but on the second day he was comfortable, and subsequently suffered no inconvenience. On examination it was found that the tumor had reached nearly the size it had before any of the tappings had been performed, and the scrotum was decidedly œdematous and tender. In order to relieve the tension, Dr. Stimson withdrew nearly 100 grammes of highly coagulable liquid, and the patient then went on to rapid recovery. Six weeks after the operation the cyst of the hydrocele had entirely

disappeared. Dr. Stimson suggested that an improvement upon the method would be to use a small amount of chloride of zinc, after removal of all the contents of the sac, in order to avoid coagulation of the albuminous material, which required considerable time for its removal by absorption.

Dr. Post had been in the habit of treating simple hydrocele in children, when stimulating lotions and acupuncture had failed, by the introduction of a single thread of saddlers' silk, which was withdrawn as soon as a fair amount of inflammatory action was produced; for, if left longer, it sometimes set up excessive inflammation. According to his observation, when the thread had not been allowed to remain in position more than twenty-four hours, excessive inflammation had not followed. The cases which did not yield to stimulating lotions or acupuncture, however, were exceptional.

Dr. G. A. Peters had always found acupuncture sufficient to effect a cure in young children, and he had cured one case in an adult by the same method.

Dr. Pilcher said that in one of his earlier cases, occurring in children, he introduced a single thread of silk; and, although it was allowed to remain less than twenty-four hours, the reaction was excessive, and gangrene of all the parts in the neighborhood occurred and caused the death of the patient.

With regard to pure carbolic acid, he had used it in one case. The result was painless, and the cure rapid and apparently complete.

Dr. Briddon thought that the use of the seton in the hydrocele of children was a dangerous procedure, and that injection would be equally dangerous. The acupuncture had always succeeded in the cases which had come under his care. He had had gangrene occur in one-half of the scrotum after tapping, and that without any accident whatever during the operation. The patient was a boy, nine or ten years of age. The cure, however, was perfect.

Dr. Post referred to a case in which Sir Astley Cooper injected a hydrocele, in an old man, with port wine, and the patient after the operation went on a journey, and had an excessive inflammation which destroyed his life.

The President thought it an important question to be decided, as to whether or not it was justifiable to resort to measures which are severe and dangerous in the treatment of hydrocele occurring in children. For himself, he had always adopted the simple methods, and had not seen undue reaction, nor failed to see the recovery take place.

SEPARATION OF THE UPPER EPIPHYSIS OF THE FIBULA.

Dr. L. A. Stimson presented the upper portion of the fibula, with the following history:

A child, eighteen months old, was run over by a horse-car, and received injuries which caused its death a few hours afterward. The right leg was badly lacerated, and the knee-joint was opened upon the outside. The upper epiphysis of the fibula was completely separated from the shaft. The specimen was interesting with reference to two points: 1, the upper end of the shaft of the fibula was entirely denuded of periosteum. He had seen that fact recorded in two other cases, and, perhaps, it had something to do with the not infrequent occurrence of suppuration after such an injury. The periosteum remained adherent to the epiphysis; 2, the separation was clean, and without fracture of the bone proper, and occurred at the junction of the epiphysis with the shaft.

Dr. Stimson also completed the history of a case of

EPITHELIUM OF THE PENIS

which he had reported to the Society. [See Medical Record, vol. xix., p. 389.] About three weeks ago the patient presented himself with a return of the disease, apparently in the right crus, forming a tumor as large as a man's fist, spreading beyond the median line to the left, and well down into the perineum, but not interfering with urination. On examination through the rectum it was determined that there was no disease behind the arch of the pubis. The man had had no trouble with urination after the first operation. Dr. Stimson decided to undertake the removal of the return growth, and the operation was performed April 20th, by making a median incision, dissecting back to the right ramus and under the arch of the pubis. In making this dissection he burst the sac, which proved to be filled with soft, cheesy contents, that were evacuated very rapidly, and he then removed the mass piece-meal The disease was confined exclusively to the right crus. The dissection left the anterior face of the triangular ligament perfectly clean. He saved a stump of the urethra long enough to bring out at the lower angle, and secure it half an inch in front with stitches, leaving only the floor of the urethra, as the roof was damaged in the removal of this mass. The case progressed favorably, without inflammatory or other reaction, and the patient was discharged apparently cured. The point of special interest was the return of the disease after removal of the penis at least two and one-half inches above any diseased tissue. At the original operation, the penis was removed at the bifurcation of the corpora cavernosa. The disease returned in only one of the crura although both were involved in the glans. At the time of the first operation the glands in both inguinal regions were enlarged and hard, but the man said that they had been in that condition for several years before anything wrong with his penis was noticed. At the second operation, fifteen months subsequently, they were in the same condition as at the first.

OXALATE OF LIME CALCULUS.

Dr. E. L. Keyes presented the calculus material removed by rapid lithotrity from the bladder of a boy, nineteen years of age, who was referred to him by Dr. Vondy, of Jersey City. It weighed four hundred and forty-three grains, and he thought that the entire stone weighed one ounce. It was pure *oxalate of lime*. The operation occupied thirty-two minutes. The largest grasp was one inch and a fourth. Although he used a two-inch wheel—unusually large—the stone was crushed with a good deal of difficulty. The débris was removed without trouble through a No. 16 tube. It was the largest oxalate of lime calculus he had ever encountered.

The Society then proceeded to the transaction of miscellaneous business.

Cultivation of Cinchona in the United States.—Hon. S. J. Randall introduced the following resolution into the House of Representatives. It was unanimously adopted:

"*Resolved*, That the Commissioner of Agriculture be requested to inform this House whether any portion of the United States is adapted to the growth of cinchona."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, June 26, 1882.

DR. F. R. STURGIS, PRESIDENT, IN THE CHAIR.

LEPROSY.

DR. H. G. PIFFARD presented a patient with the following history:

Mishikawa Lakichi, thirty years of age; Japanese; single; porter. Was admitted to Charity Hospital May 20, 1882. The patient's previous and family history was not obtainable, save in a very imperfect and fragmentary way, from a friend who understands a few words of English. From what could be obtained, the family record seemed to be a good one, no skin affection in any way like his own being traceable. He has lived all his life, until two years ago, in Japan, where he was a farmer. Soon after he came to New York, and has lived here ever since, working as a packer in a Japanese store. He himself denies syphilis, or any other serous disease. There is, however, a vague history of a gonorrhœa and bubo ten years ago. Six weeks before admission he fell sick. At that time spots appeared on his body, first on the legs, and then on arms and trunk. These spots, he says, came quickly —in a week the eruption was fully developed. After being sick a month he went to the New York Hospital, where he remained two weeks as a case of leprosy, and was then sent here. He himself thinks he has syphilis, though he says he has not had intercourse for ten years.

May 21st.—Diagnosis not fully made. Tr. quinine, gr. x., and iodide of potassium in small doses. Temperature, 101° F. Swelling and redness of face, looking like commencing erysipelas; also redness of chest, extending a little below the nipples. Some swelling and redness on hands and feet, in spots, especially left hand, which is stiff and swollen. ℞. Lot. plumbi et op., for face and chest.

From this time till June his temperature was 99½° to 100° F. Never over 100° F. after first few days.

Treatment: Quin., gr. i.; pot. iodid., gr. v., t. i. d.; pb. et op. wash.

Under this his erysipelas gradually disappeared, the eruption remaining about the same, save that the redness and swelling went down a little. There was a little desquamation on the chest and hands; none on the face. His general condition was fair.

June 1st.—Much improved. Temperature normal. Skin desquamating from hands, which, especially the left, are still sore. Facial redness going away. Appetite fair; bowels regular.

Dr. Piffard also read the following of another case, which was in the same hospital:

James E——, nineteen years of age; single; born in the West Indies, and a painter, was admitted December 2, 1880.

Family history.—Patient was born in Bermuda, and resided there one year after birth. From thence he was taken to Norfolk, Va., where he remained six weeks. From thence he was taken to Baltimore, where he has lived until he again went to the Bermudas, two years ago. Three weeks ago he returned from there. Has not been in any other localities. His father and mother are living and healthy.

Previous history.—Health has always been good. Had asthma when young. Says he has never seen any one affected with leprosy. Denies venereal altogether. Worked at his trade as a painter while in the West Indies.

Present history.—As near as the patient can recollect, his present trouble began two years and nine months ago, about one year before he went to Bermuda. The first thing he noticed was a numb feeling in the plantar surfaces of both great toes. Next brownish rings appeared on the posterior portion of both forearms; they were not elevated above the surface. These spots and rings gradually fused into the large plaques which at present can be seen on his arms. At the present time they cover the whole of the extensor and supinator surfaces of both forearms and arms. At various points these plaques have tubercles scattered over them; various white spots also, one-fourth of an inch in diameter, are scattered over these surfaces. Some of these tubercles, but only a few, are analgesic and anæsthetic. On the ulnar sides of the hands, on the portion lying over the outer side of the fifth metacarpal bone, we find analgesia and anæsthesia. No ulceration has occurred since the disease began. The *hands* are only anæsthetic and analgesic as above, but the rest of the cutaneous surfaces of the hands is quite livid and feels unnaturally smooth. Patient has not noticed the brownish discoloration which is present to a small extent on the body and legs. He says that one of the first symptoms of the maculation on his arms was a great heat in them. On the *legs* the maculation is especially marked posteriorly. Some papules are found there, but no tubercles. There is slight anæsthesia there. On the *back* the eruption commenced as a maculation, occurring in annular form, these maculæ gradually fusing together to form the large plaques now present. On the *face* the process began as on the back. In both situations, after a while, tubercles began to form. They are now quite abundant over the malar bones, and over the lower part of the frontal bones. They are less marked upon the back. The tubercles on his forehead give a well-marked leonine expression to his countenance. In the right frontal region especially the tubercles are fused together to form tubercular plates of considerable size. The pigmentation on the face is not as marked or of as deep a brown color as it is on the rest of the body. There is no analgesia or anæsthesia of any of the face-lesions.

The patient's general health is good.

December 14th.—This afternoon patient complained of chilly sensations along the spine; these were followed by a decided febrile movement, which lasted all through the night. No other symptoms. No twitching of the limbs.

December 15th.—Feverish. Remained in bed all day. Some anguish and general rheumatoid pains. No twitching.

December 16th.—Vomited to-day. Anorexia marked. Pains somewhat better. Temperature, 105° F. in P.M. Ordered cathartic.

December 17th.—This morning, temperature 105½° F.; pulse, 130. Marked infiltration of the skin on the right side of the face, especially over the malar bones. The skin is not much reddened, but its surface is hot and it is irregular, from the development of small tubercles and papules, especially about the root of the nose. There is some burning pain in the inflamed parts. Some cough. Examination shows the hard and soft palate in the same condition as is the skin.

December 19th.—Temperature, 105⅝° F. at 12 A.M. Surface of face that is swollen is studded with vesicles and pustules in groups. Sent to the pavilion by Chief of Staff.

December 28th.—Returned from pavilion. The

tubercles from the forehead, ears, and chin have disappeared; otherwise, condition about the same.

January 7, 1881.—Treatment: hoang-nan, gr. ½, t. i. d. Some anæsthetic spots on legs. Sensation is returning to little fingers of both hands. Tubercles of face and ears are very much diminished in size.

January 22d.—Nocturnal emissions, which were rather frequent when he first entered the hospital, have become less common (from five or six to one a week). Tubercles on the face and ears decidedly diminished in size. Anæsthetic spots about the same as before. Tubercles of body unchanged. Treatment: hoang-nan, gr. ½, four times a day. Use of salt meat and alcohol in any form forbidden.

February 5th.—Tubercles of face diminished still more; maculation less apparent. No emission of semen for two weeks. Treatment: hoang-nan, gr. ½, four times a day.

February 19th.—Tubercles still diminishing in size. Fresh groups of pustules on tubercles of the chin and rami of jaws. On the external condyle of right leg is a fresh, irregular patch of tubercles, one and one-half by one inch in diameter. Treatment; stop hoang-nan and use tinct. ferri chlor., ℥ v., t.i.d. Suppuration under nail of second toe, left foot. No injury.

February 22d.—12 A. M., temperature, 104½° F.

February 23d.—Temperature, 101° F. Face is flushed, and he complains of headache and general febrile symptoms again.

February 24th.—12 A. M., temperature, 103¾° F.; pulse, 88.

February 25th.—Temperature, 102½° F.; pulse, 80. Treatment: tinct. aconit. rad., ℥ ij., every two hours. Feels better this morning. Increased swelling of the prominences on the forehead and on the malar bones. Swollen parts have a purplish hue.

February 26th.—Some headache. Tongue furred and yellowish. 12.30 P. M., temperature, 104° F.; pulse, 72, and full; respiration, 26. Skin hot and dry. No fresh tubercles. Says that the numbness of his feet is worse. Treatment: hoang-nan, gr. ⅒, t. i. d.

February 28th.—11 A. M., pulse, 72; respiration, 24; temperature, 102½° F. Perspiring profusely. Says he feels better.

March 1st.—11 A. M., temperature, 103¾° F.; pulse, 76; respiration, 28.

March 2d.—3 P. M., temperature, 103¾° F.; pulse, 80; respiration, 32. Face flushed. Feverish. Very restless at night.

March 3d.—11 P. M., temperature, 103½° F.; pulse, 96; respiration, 28.

March 4th.—12.30 P. M., temperature, 100° F.; pulse, 68; respiration, 24.

March 5th.—11.15 A. M., temperature, 102° F.; pulse, 80; respiration, 24. Complains of sweating at night. The hot and dry skin present a week ago has disappeared, and he feels much better.

March 8th.—Headache, and much perspiration.

March 16th.—On March 10th his fever subsided. During its continuance his hoang-nan was stopped. From March 10th to 15th it was resumed, in one-tenth grain doses t. i. d. No febrile excitement since March 10th. The tubercles of his face are one-third their former size; those on the malar prominences have disappeared; pigmentation also less.

March 26th.—His face is gradually getting cleaner and brighter. The tubercles over the body are generally much less in size, and the maculation is apparently being absorbed without any such atrophy as was noted in the case of Henkle. All over the body the tubercles show signs of absorption. The pigmented surfaces are clearing, the numbness of the arms and legs disappearing. The number of his seminal emissions has diminished to one in four weeks. The parts that were, on January 7th, noted as anæsthetic, are gradually recovering their sensibility.

March 31st.—Improving. Treatment: hoang-nan internally, and ol. chaulmoogra externally.

Through the rest of this year, and the first part of the next, Evans remained in fairly good health. He worked in the open air most of the time. The same treatment was continued, but the condition of his skin did not undergo much change after April, 1881.

January 4, 1882.—Yesterday suffered from an attack of facial erysipelas, involving chiefly left side of face, forehead, eyelids, and cheek. Temperature slightly raised; pulse, 120. General febrile symptoms. Treatment: mask and lot. pb. et opii, and tinct. ferri chlor. internally.

January 15th.—A.M., pulse 120. Fever has been more or less continued ever since last note. The inflammation is now extending over the other side of face. Treatment same; also cinch. sulph., gr. x., t.i.d.; P.M., the other half of the face, nose, ears, eyelids, lips, etc., are involved. Pulse rather feeble. Treatment continued, with whiskey and milk.

January 16th.—Whole face is involved in the erysipelatous inflammation. Pulse, 114, feeble and soft; temperature, 105½° F. in axilla. Treatment: milk diet, moderate stimulation; cinch. sulph., tinct. ferri chlor. internally, and lot. pb. et op. externally. 12 P.M., temperature, 104° Fahr.; pulse, 120, and feeble.

January 17th.—Pulse, 90; temperature, 104°; respiration, 24. Swelling commencing to go down. Treatment: tinct. benzoin co. painted to face; stop lot. pb. et op.

January 23d.—The erysipelas has gradually subsided, leaving him well but very weak. Pulse, 70; temperature, 100½° F. in axilla. Treatment: tonic and stimulant.

January 31, 1882.—No new spots or tubercles have been developed by his erysipelas, nor is there any change in the anæsthetic or numb regions. There is, perhaps, a slight increase in size of the tubercles on his forehead.

Remarks.—Commenting on the subject, Dr. Piffard directed attention to the views entertained by Drs. Fitch and Emersen, of Honolulu, Hawaiian Islands, where leprosy has been seen in abundance. The chief point of interest to which reference was made was the relation of the disease to syphilis. To make the differential diagnosis was very frequently exceedingly difficult. In this connection a letter was read from Dr. Henna, of New York, who had seen considerable of leprosy, and in which mention was made of the great difficulty in distinguishing between the two affections in many cases. Reference was then made to Dr. Fitch's views, who believes that leprosy is simply the *fourth* stage of syphilis. Dr. Fitch is in charge of a large branch hospital for lepers in Honolulu, Sandwich Islands, and from his observations has given the general proposition: "Leprosy is the *fourth* stage of syphilis, which white men are exempt from in the vast majority of cases. When the syphilitic scourge appeared in Europe in the latter part of the fifteenth century and the beginning of the sixteenth, it spread throughout entire Europe, probably infected nearly everybody, and acted as an inoculation itself, so that those who acquired the disease afterward were less liable to its

severe forms; but that where syphilis attacks those who have not been syphilized through their ancestry, the disease may go on to the development of the fourth stage of the disease, or leprosy." Such is Dr. Fitch's general proposition, and he believes that, *without exception*, syphilis precedes leprosy.

Dr. Piffard said that the fact seemed to be that in the Sandwich Islands the great majority of the natives have suffered from acquired syphilis; but that a certain proportion—probably six or seven out of ten—also have leprosy.

There is nothing in either disease which will prevent the development of the other, as has been proved by experiment. He regarded it as not at all surprising that Dr. Fitch had met with cases in which the chief features of the two affections were very much alike. At the same time the history of the cases, as in the case of the Japanese presented, might be unsatisfactory,

Dr. Piffard then read the following questions asked him by Dr. Emerson, and answered them seriatim:

First.—"Do you find any cases of leprosy occurring absolutely without a previous leprosy intimacy, or under circumstances such as forbid you to think it must have come from such intimacy?"

The disease is not contagious in the ordinary sense of the word; that is, is not conveyed by simple contact, but it probably is propagated by blood or some of the secretions gaining access to the circulation and absorbents of an unaffected person. There is but little doubt that leprosy has been propagated by vaccination, and sexual intercourse. There is also but little doubt that it is hereditary. During the last twenty years a good many lepers have been in New York, several have been in hospitals, but the first case of leprosy developing in a *native* of this city has yet to occur. He had known of only two cases developing in the city, and in both of those the patients had previously lived in countries where leprosy existed. As to whether any cases occur absolutely without previous leprous intimacy, he had seen only one, and that occurred in the practice of Dr. H. D. Bulkley, and was declared by Börck, of Christiania, to be genuine.

Second.—"Do you find lepers who have no previous history of syphilis?"

In the majority of cases he had seen, a clear history of syphilis could not be made out.

Third.—"Do you find cases of leprosy occurring in patients previously syphilitic, under such circumstances as to lead you to believe the leprosy comes from the syphilis?"

This question was answered in the negative.

Fourth.—"Do you find any cases or facts that lead you to think that syphilis may change into leprosy?"

The answer was, No; none at all.

Fifth.—"Does not the microscopic pathology of leprosy differ widely from that of syphilis?"

There is no question but what it does.

Dr. Piffard then gave the distinguishing features of the two affections, and concerning the *bacillus leprœ* recently described as the cause of the disease, he believed there was very great doubt as to its being an etiological factor.

He thought that Dr. Fitch was undoubtedly wrong in his view that the two conditions were simply two stages of the same disease, namely, syphilis. The idea that leprosy is nothing more than the fourth stage of syphilis, and that syphilis would develop into leprosy, he thought would not hold for a moment.

In conclusion, he remarked that as our intercourse with foreign nations extends we are getting more and more cases of leprosy, and wherever it gains a foothold it spreads, and therefore he regarded it as important that some means be applied by which persons with the disease could be isolated, be kept together, so as to prevent its spreading.

Dr. A. Jacobi asked, why isolate if the disease is not contagious?

Dr. Piffard said it was well-known that wherever lepers settle there is more or less of the disease found afterward. We do not know the special means of communication, to be sure, but doubtless isolation would reduce the number of cases, as it would syphilis. The weight of evidence seems to be in favor of the view that it is propagated as is syphilis.

Dr. Jacobi remarked that leprosy was not indigenous in this country, but came only as it was imported, and he did not think that fact would necessarily include the isolation of the persons affected. The question was not only practical but theoretical, for in its answer would be included some part of the nature of the disease. Is it contagious, or not? Is there anything in these nodules which can be communicated? He thought it would be a long time before it would be proved that the *bacillus leprœ* was the entity of the disease.

Dr. E. G. Rawson referred to a case which he saw in 1838, several times. It was called a case of leprosy, but there was no evidence that it was contagious. The entire body was covered with large dry scales. Perhaps it was syphilis. He thought it well, however, to keep this class of patients separated from others.

Dr. J. H. Low referred to a case of *lepra* which he had reported in the *Southern Medical Monthly*, and in which the characteristic feature was the formation and dropping off of excessive quantities of large dry scales.

Dr. Piffard was asked if he had seen leprosy occurring before puberty.

He replied that he had seen one case, occurring in a child between nine and ten years of age, and as the result of vaccination.

With reference to the nomenclature of leprosy, there had been some confusion.

The disease described by English writers under the name "elephantiasis Græcorum" is the leprosy of the present day.

There is another affection which Continental writers describe under the name *lepra*, but which is the psoriasis of the present day.

The symptomatology of the two diseases was distinctly given by Hippocrates and others.

In the Old Testament writings reference is made to a disease which has been translated by the word leprosy, and in which the symptomatology is that of elephantiasis G. On the other hand, the Greek word, in the New Testament, translated leprosy is lepra, and the persons called lepers suffered from psoriasis.

Probably the case reported by Dr. Low was one of psoriasis, and also that referred to by Dr. Rawson.

In answer to the question, What is the average duration of leprosy?

Dr. Piffard answered that it was about ten or twelve years Psoriasis, on the other hand, does not shorten life at all.

Dr. O. B. Douglas referred to a case which he recollected as one *said* to be of leprosy, and in that instance the disease was scaly rather than having the appearance of that upon the patient presented by Dr. Piffard. Several of the children inherited

the disease from the father, but so far as he knew the mother was healthy.

The President discussed the subject at some length, with special reference to the differential diagnosis between leprosy and syphilis. Although leprosy, like syphilis, attacks nearly all the tissues of the body, skin, bone, nerve, and the eyes, etc., yet, throwing aside the initial lesion of syphilis and coming to the secondary eruptions, there are sufficient differences between the maculæ, the papules, the tubercles, etc., of the one and those of the other, to establish a differential diagnosis. Again, the anæsthesia is a feature of leprosy and not of syphilis, and the dry necrosis of leprosy differed from the necrosis of syphilis in that the latter was nearly always attended with abundant suppuration.

Dr. Sturgis was of the opinion that in many cases the so-called erysipelas occurring in leprosy was nothing more than true leprous fever. Every fresh outbreak of tubercles is usually preceded by high fever, loss of appetite, etc.

He regarded leprosy and syphilis as two entirely distinct diseases.

With reference to isolation, it had been advocated not so much on account of the question of contagion as for the sake of the patients themselves. Patients with leprosy become absolutely helpless, and as a matter of humanity they need some special provisions for their care. Besides, it seems well established that occasionally it has been conveyed by means of drinking-vessels.

He thought it could not be laid down too strongly that leprous affections are not desquamative. Where there is a marked, scaly eruption the case should always be regarded as extremely suspicious and the closest possible scrutiny exercised with reference to the existence of syphilis.

Dr. Sturgis then directed attention to the beneficial effects produced by chaulmoogra oil, and also the good results obtained by the use of hoang-nan, which relieved but did not cure.

The subject of isolation was further discussed by Drs. Jacobi and Piffard, after which the Society adjourned to meet the *fourth* Monday in September.

Significance of Tube-Casts in Bright's Disease.—Dr. J. S. Richardson, of Philadelphia, in a paper read before the Philadelphia County Medical Society, on January 31, 1882, takes a stand opposed to that held by Charcot and others, in his estimation of the importance to be ascribed to the casts found in the urine. He maintains that the scanty flow that is observed in some forms of Bright's Disease, is accounted for by the mechanical obstructions offered by the casts in the tubes. He also invites attention to what he called "mucous casts," long and branched bodies found when the bladder is irritated. They sometimes have leucocytes attached. The casts shrink in a solution of the acetate of potassa, a diagnostic test for them. Where there is question as to the fatty nature of the granules in casts, Dr. R. suggests the use of an osmic acid solution, which colors them black. Dr. Tyson, in commenting on the paper, sustained the more common theory that hyaline casts are fibrinous in their nature. Dr. Formad advanced his belief that even the hyaline casts may become granular after the expiration of a few days; sometimes they are granular from the presence of bacteria, though this cause did not appear to have been often suspected.—*Philadelphia Medical Times*, May 20, 1882.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 6, 1882.

Dr. E. C. Spitzka, President, in the Chair.

Dr. Græme M. Hammond presented a case of

ADDISON'S DISEASE

in a young woman whose sister at the same time was suffering from progressive muscular atrophy.

The patient with Addison's Disease was about twenty-six years of age. She had been suffering for over a year, and had been growing thin and weak. She had occasional remissions. The arms, body, and face were bronzed in different degrees. The nails were non-elastic. The mind was less bright than formerly; the temper irritable.

The sister had suffered from progressive muscular atrophy for about two years. Eighteen months ago she had complete paralysis of the palate, and the muscles of deglutition were markedly impaired. The lips protruded; she soon got tired when talking. The paralysis later invaded the arms and legs. At the present time she falls occasionally when walking. The faradic reaction was normal. The treatment had been static electricity, under which she had markedly improved.

Dr. E. C. Seguin related the case of a young lady with symptoms resembling progressive muscular atrophy. There was a paresis affecting the muscles of the face, the levator palpebræ, the lingual and pharyngeal muscles. Deglutition was difficult. The arms and legs did not suffer at all. The patient was chloro-anæmic. Electrical reactions were normal. The patient improved steadily under strychnia and phosphoric acid. The speaker was unacquainted with progressive muscular atrophy, beginning in the way described by Dr. Hammond, except in children. He had never seen a case occurring in women of the age of Dr. Hammond's cases. He suggested that it might be a case of chronic poliomyelitis.

Dr. Græme Hammond could not admit that diagnosis in his case. He had two cases of progressive muscular atrophy under treatment, of about the same age with the present patient.

A paper was then read by Dr. N. E. Brill, entitled

REPORT OF A CASE OF DESTRUCTIVE BRAIN LESION ACCOMPANIED BY COLOR-BLINDNESS.

The patient in this case was a man who rather suddenly developed brain symptoms. There was anæsthesia and paresis upon the right side, the loss of sensation being more marked than that of motion. The right hand was paretic.

The urine was alkaline and contained pus but no albumen. Tendon reflexes were more marked on the right side.

After a few weeks symptoms of irritation appeared; hyperæsthesia, restlessness, tinnitus aurium, mind not clear. There was slight amnesic aphasia. Color-blindness developed. He could not tell green from red. There was no limitation of the field of vision. Hemiplegia became well marked. Tremors were present. Patient gradually declined in health and died.

Autopsy.—The brain only was examined. The cerebral branches of the carotid and vertebral arteries were found to be healthy. The internal carotids had very rigid walls. Membranes normal. A focus of softening, triangular in shape, was found in the cuneus on the left side. It involved a large part of

that convolution. The line of softening was very sharply marked from the healthy tissue, so that the case was one of very purely localized softening. A diagram showing the lesion was displayed. The reader of the paper then went over the literature of the subject, and gave a critical analysis of previous cases reported.

The paper being open for discussion,

Dr. Hermann G. Knapp said that he was unable to discuss this paper. It was completely at variance with what he knew about the subject. He wished that the reader had mapped out the visual field. It was, he thought, impossible to conceive of a separate centre for color perception. He thought, however, that here was a subject for neurologists to work out.

The paper of the evening was then read by Dr. Leonard Corning. It was entitled

CAROTID COMPRESSION AND PHYSIOLOGICAL BRAIN-REST.

[The paper is published in full elsewhere in The Record.]

The paper being open for discussion,

Dr. Wm. A. Hammond said that while it was necessary to admit the practical facts given by Dr. Corning, he was unable to explain why carotid pressure should check an attack of epilepsy. The primary condition, as we know, in these attacks, is one of contracted vessels and anæmia. Some time ago he had heard of persons stopping fits by putting rubber bands around the neck. But this was for the opposite purpose of checking the venous flow and thus causing congestion.

Dr. L. C. Gray said, in reference to the supposed primary anæmia of epilepsy, that experiments on animals had showed that there was no absolutely constant vascular condition of the brain at that time. So far as the evidence now goes, the vascular spasm is an effect, not a cause.

Dr. Græme M. Hammond related the case of an epileptic child, thirteen years of age, which had an aura, lasting about half a minute. He tried carotid compression on one occasion, with the result of completely stopping the fit.

Dr. M. J. Roberts related several cases in which he had used Dr. Corning's method and instruments successfully.

The first was a case of

CONGESTIVE HEADACHE.

The patient was suffering intensely with severe pain, suffused eyes, etc. A compressor was applied and in forty-five seconds the pain had ceased. The second case was also one of congestive headache, the speaker himself being the sufferer. He applied the truss and in fifteen or twenty minutes he felt relieved and slept.

The third case was one of profuse hemorrhage, following removal of an anterior nasal polypus. The patient was somewhat alarmed. He applied the compressor to the carotid. To his surprise the hemorrhage ceased in one or two minutes.

He had used compression in connection with the administration of ether in ten or twelve cases. In all it seemed to have some decided effect.

The quantity of ether needed was apparently less, and the patients did not struggle so much.

The speaker had used digital compression in the case of a child suffering from convulsions. He was able in this way to control the spasms.

Dr. Corning made a few concluding remarks.

The Society then adjourned.

New Instruments.

A FINGER ELONGATOR.

By JOHN B. RICHARDSON, M.D.,

LOUISVILLE, KY.

On April 8, 1880, I was in attendance upon the case of miscarriage which suggested to me my "finger elongator." Wrote the accompanying article on same and sent it to Dr. Paul F. Mundé, editor of the *New York Journal of Obstetrics*, for publication. October 22, 1880, received answer from Dr. Mundé, stating: "I have been absent during the summer, but your article with diagrams had been sent me by my publishers and later your letter," which had been mailed at same time. He requested me to send the instrument to him, as he wished to test its value before publishing. On March 11, 1881, he again wrote me, apologizing for having lost my instrument. On March 18, 1881, he wrote regretting that "my journal is so full of matter, and it hardly seems fair to ask you to wait till July number of my journal appears for me to publish your article," and advised me to have it published in a weekly journal like The Record. I then sent article to Dr. Geo. F. Shrady, of The Record. He replied under date April, 1881: "Will you kindly send me a model of your 'finger elongator' for examination? If it is as useful as it appears to be I will, with your consent, ask Tiemann or Reynders to manufacture them," etc. On April 3, 1881, Dr. Shrady wrote me: "Tiemann & Co. have made a model of your instrument. Please write to them and ask them to send you one for approval." I was absent for the summer of 1881, in Wisconsin, but whilst there I received of Tiemann & Co. one they had made; this I returned for some alterations. After this I heard nothing from either Dr. Shrady or Tiemann & Co., until April 21, 1882, when the latter wrote me: "The mechanic in whose hands we had placed the instrument for perfection had died of consumption, and that he (Tiemann) had supposed it had been made and sent you long ago. We will make it at once and send for your approval." May 17, 1882, he sent me model. A few days later I returned model to Tiemann & Co. to make further alterations, and wrote Dr. Shrady to publish article. The same day I was surprised to find in the *New York Medical Gazette*, of May 13, 1882, an article by Dr. F. N. Otis, describing an instrument involving the same principle upon which my finger elongator is based. In the latter part of this notice these words occur: "The same appliance promises also to prove of service in removing foreign bodies from the throat, as well as exploration of the uterus."

My instrument, as will have been observed, had been in the hands of Dr. Mundé three weeks prior to October 22, 1880, and in the hands of his publishers some weeks before he received it at their hands, and after that in the possession of Tiemann & Co. from November 12, 1880, and, as he informed me May 17, 1882, "fits my finger exactly, and most all who were here found that it fitted their index finger." It is well known by Mr. Graham Wilder, who made two of my models; Mr. Adolph Fisher, instrument maker, who made my first model; Dr. J. A. Octerlony, who was my counsel in the case of miscarriage which suggested the idea of elongat-

ing the finger to me; by Dr. David Cummins, Dr. John Goodman, Dr. W. W. Senteny, Dr. D. Morton, Mr. Julius Bamberger, and my brother, Samuel B. Richardson, of this city, to whom I exhibited my instrument about July, 1880; to Dr. H. Lyman, of Chicago, who saw it in September, 1881, and Dr. P. F. Mundé, Dr. Geo. F. Shrady, and Tiemann & Co., of New York City, who saw it 1880 and 1881, and know that the idea was an original one and was mine, and would have been published in 1880, but for the fact of the unfortunate delay caused unavoidably by Dr. Mundé and Tiemann & Co. I claim priority for both the idea and its practical application. The following is the article sent to Dr. Mundé in 1880 and Dr. Shrady in 1881, and bears date of July, 1880.

JOHN B. RICHARDSON.

LOUISVILLE, KY., June 1, 1882.

Feeling the want of some means or mechanical device, by which the index or "searching" finger might be elongated, thereby enabling us to make deeper digital examinations than the length of the natural finger permits, and at the same time allow the extremity of the finger to receive impressions made upon the terminal end of such instrument, the following described contrivance suggested itself, some time since, during my attempts at the removal of a remaining portion of the "secundines," in a case of abortion, at the end of the second or beginning of the third month of gestation, the loss of blood being so great before I reached the patient as

Fig 1.

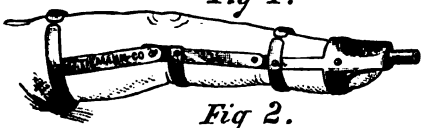

Fig 2.

to jeopardize her life, her pulse at the wrist being lost, and her respirations much "slowed," sighing, and irregular. More than twenty years ago, I had seen an instrument used by my father—the late Dr. Samuel B. Richardson of this city—to remove portions of "membranes" remaining, which could not be reached by means of the unaided finger; it was composed of a small copper wire, curved upon itself, and of the proper length and strength, as to enable him to introduce it into the uterine cavity, by holding the lower ends between his thumb and index finger, very carefully and gently remove the portions of membranes and blood clots which remained and were keeping up the hemorrhage. As will be observed from the accompanying cuts (Figures 1 and 2) the instrument consists of two parts or pieces. The first part is composed of a very thin silver cap or thimble, which should accurately fit the contour of the end and sides of the finger upon which it is to be used, a plaster cast of the finger being first taken, then a metal mould from this "cast," upon which metallic form the silver finger cap is perfectly fitted; passing from the lower border of the thimble are two thin and narrow lateral metallic pieces, of proper length to reach beyond the second joint of finger, having artificial joints opposite the true joints of finger. These lateral metallic pieces are held together and made to embrace the finger by steel bands or rings, which surround the finger at points midway between the first and second and second and third phalangeal articulations.

Upon end of finger-cap or thimble there is placed a receptacle into which can be secured, by means of screw, any of the attachments to be hereafter mentioned.

The *second* part consists of a small silver, copper, or steel wire, so curved upon itself as not to injure, during its employment, any of the tissues with which it comes in contact; when made of copper wire, it can be changed to any curve desired.

Having adjusted the instrument accurately upon the finger, you will find, after a little practice, all degrees of pressure, made to impinge upon the terminal extremity or sides of any of the attachments used, are immediately transmitted back upon the sensitive end of the finger through means of the cap or thimble; so accurately is this done, that the terminal end of the artificially elongated finger is only surpassed, in its delicacy of appreciation of touch, by the true end of the natural finger, thus enabling the accoucheur to remove all coagulæ or portions of the secundines remaining within the uterine cavity, which are beyond the reach of the unaided finger, and yet not injure the uterine structure.

Nor is this little instrument limited to the use above pointed out, for removing the incurvated wire attachment, by unscrewing it from receptacle in end of finger cap, you can screw firmly in its stead the stem of a "Sims' uterine replacer," and by its use rectify a displacement of the organ, more fully appreciating both the extent and degree of force exerted whilst using "Sims' replacer," grasped between the thumb and fingers at the end of its long handle; or a Thomas' dull wire-curette can be attached for rupturing enlarged follicles within the uterine cervix, which have undergone cystic degeneration.

Further, the Sims' stem can be removed and an uterine applicator secured in its place, with which any intra-uterine application can readily be made after dilating cervix; or a stem, with an eye in its distal extremity, can be used after threading with silk or wire, thus enabling the operator, with much greater facility, to pass it around the pedicle of an intra-uterine polypus or pedunculated tumor.

Another use, it occurs to me, to which it might be adapted is after elongating finger by incurvated steel wire (flattened) attach to its extremity one of "Emmet's enucleators," with serrated edge, for removing fibrous intra-uterine growths.

The curved wire might materially aid the surgeon in his searchings for the location of a calculus in the bladder, through the urethra, after it has been forcibly dilated, in the female; or through the incision made in the operation of lithotomy, in the male; or a vertebrated or other probe attached to the "cap," would enable one to more accurately and safely explore a deep and tortuous sinus or some deeply imbedded foreign body—a Nélaton porcelain tip placed on probe in searching for leaden missiles.

The instrument I possess was kindly made for me by my friend, Graham Wilder, Esq., of this city, to whom I am indebted for some practical suggestions toward improving the usefulness of the instrument, one of which is to use two narrow, metallic ribbons, with artificial joints placed opposite joints of the finger, as a substitute for finger cap or thimble.

July, 1880.

DR. KEITH, it is said, has sent his son to this city to finish his gynecological education.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from June 25, 1882, to July 8, 1882.

By direction of the Secretary of War, the Medical Examining Board, convened in New York City by S. O. No. 223, October 30, 1877, from A. G. O., is dissolved, to take effect June 30, 1882, and the following named officers now members of the board will report by letter to the Surgeon-General:

Major JOSEPH B. BROWN, Surgeon.
Major JOSEPH H. BILL, Surgeon.
Major CHARLES H. ALDEN, Surgeon.
S. O. 147, A. G. O., June 26, 1882.

DELOFFRE, A. A., Capt. and Asst. Surgeon. Relieved from further duty at Ft. Wallace, Kans., and assigned to duty at Ft. Sill, Ind. Ty. S. O. 124, Dept. of the Missouri, June 21, 1882.

GARDNER, E. F., Captain and Asst. Surgeon. Relieved from duty at Vancouver Barracks, W. T., and assigned to duty as Post Surgeon at Fort Cœur d'Alene, Idaho. S. O. 83, Department of the Columbia, June 19, 1882.

BANISTER, J. M., 1st Lieut. and Asst. Surgeon, when relieved by Asst. Surgeon DeLoffre, to proceed to camp of 9th Cav., near Cantonment on the Uncompahgre River, Colo., and report to the Com'd'g Officer for duty. S. O. 124, Dept. of the Missouri, c. s.

O'DONNOGHUE, F., Captain and Medical Storekeeper. Died at New York City, June 29, 1882.

HEAD, JOHN F., Lieut.-Colonel and Surgeon. Granted leave of absence for fifteen days. S. O. 153, A. G. O., July 3, 1882.

Under the provisions of Section 1 of the Act of Congress, approved June 30, 1882, the following named officers are, by operation of law, this day retired from active service, viz.:

Brig.-Gen. JOSEPH K. BARNES, Surgeon-General.
Colonel JOHN M. CUYLER, Surgeon.
Colonel WILLIAM S. KING, Surgeon.
Lieut.-Colonel JAMES SIMONS, Surgeon.
S. O. 151, A. G. O., June 30, 1882.

Medical Items and News.

ARTIFICIAL QUININE.—M. E. J. Maumene claims to have achieved the artificial synthesis of quinine, and has deposited a sealed packet describing his process with the French Academy, pending physiological tests of its genuineness. Much incredulity exists regarding his claims.

CONTROLLING QUININE.—A great combination of the quinine manufacturers abroad has been formed, for the purpose, it is stated, of controlling the market of the United States.—*Monthly Review of Medicine.*

GONORRHŒA OF RECTUM.—Dr. Morris, of Baltimore (*Maryland Medical Journal*), reports a case of gonorrhœa of the rectum in a lady; did not arise from unnatural practices. The symptoms were pain, spasmodic contraction, formication, etc. The treatment consisted in applying nitrate of silver thoroughly to the everted rectal mucous membrane.

DR. FOTHERGILL, who has seen the bacillus of tubercle imported on slides from Germany, writes a lively and satirical description of the same to the *Philadelphia Medical Times.*

THE GIFT OF DR. TONER'S LIBRARY TO THE NATION.—Dr. Joseph M. Toner, of Washington, has donated his library to the United States, the entire collection of books, pamphlets, manuscripts, and periodicals, amounting to between 20,000 and 25,000 volumes. The learned and laborious donor has been known for a quarter of a century past as a most intelligent and indefatigable collector, and his library is rich in American history, biography, topography, medical science, and scientific and miscellaneous literature.

THE NEW YORK CODE.—*Resolved*, That the Queens County Medical Society, in convention assembled, utterly repudiate section second of the revised Code, and will not be governed by it.

Resolved, That the secretary furnish a copy to the delegates at the American Medical Association and instruct them to present it to that body at its meeting at St. Paul, Minn. That our delegates to the State Society be instructed to use their influence for the repeal of the same at the State Society next meeting.

Resolved, That a copy be sent to THE MEDICAL RECORD, *The Philadelphia News*, and other medical journals for publication.

At the annual meeting of The Lewis County Medical Society, held at the Court House in the village of Lowville, N. Y., on motion of Dr. Alex. H. Crosby, the following resolutions were unanimously adopted:

Resolved, That the delegate from this society to the New York State Medical Society is hereby instructed to use all honorable means in his power to have the "New Code," adopted at the last meeting of the State Society, repealed; and further, that he shall endeavor to have a committee appointed to confer with leading members of the medical profession in every county of the State, as to their views in relation to any changes advisable to be made in the "By-laws" and "Code of Medical Ethics."

Resolved, That the above be published in the *Medical News*, and MEDICAL RECORD.

NATIONAL BOARD OF HEALTH.—The House Committee on Appropriations has agreed to insert in the Sundry Civil Appropriation bill a clause restricting the operations of the National Board of Health to the diseases of yellow fever and cholera. The amount of the board's appropriation has been cut down so that, if the appropriation bill is passed as recommended, the publication of the *Bulletin* will have to be suspended. This will be much regretted.

A POST GRADUATE SCHOOL has been established in this city. The arrangements have not yet been entirely completed.

PROFESSOR NOTHNAGEL has been called to Vienna, to take the chair occupied by the late Prof. Duchek.

LEUCOCYTHÆMIA IN INFANTS.—Professor Senator has recently presented an exceedingly interesting case of twins, girls, one year and five months old, who were affected with genuine splenic leucocythæmia, a fact established by means of a computation of the blood-corpuscles, and rachitis.

IN MEMORIAM.—The *St. Louis Courier of Medicine* for June contains a large number of memorial resolutions by various societies upon the death of Dr. Hodgen. All show how much he was admired living, and how profoundly his loss is mourned.

Original Communications.

CASES TREATED WITH PHENIC ACID (DÉCLAT).[1]

By L. M. YALE, M.D.

The claims urged by Dr. Déclat for his preparations of phenic acid are probably familiar to all the members of this Society. During and since the visit of Dr. Déclat to this city, a few cases have been treated after his plan at Bellevue Hospital. The following cases were treated by Dr. A. J. Magnin, House Surgeon of the Second Surgical Division: one is a case of pyæmia, treated during the service of Dr. Weir; one a case of high temperature (probably septic) attending compound fracture, complicated by delirium tremens, treated during my own service; and the remainder are cases of erysipelas, treated by Dr. Magnin in the detached erysipelas service. With the exception of one case of puerperal septicæmia, one of erythematous erysipelas and one of lymphangitis, all were successful in result. These are all the cases treated in the Hospital, strictly according to Dr. Déclat's method, of which I am aware. Some cases have been treated partially or imperfectly. I have not considered these, because it seems only fair to any plan of treatment or its proposer that the method should be strictly followed.

Having understood that some of my fellow-members had employed this method to some extent, I have thought it worth while to present these few cases in order to draw out their experience.

The essential claim of Dr. Déclat is that the well-known toxic symptoms that follow the internal use of carbolic acid are due less to the drug proper than to impurities very frequently present, notably cresylic and rosacic acids and rosaline; and that in making a perfectly pure acid and preparations of it, he renders possible the internal administration of carbolic or phenic acid to the degree necessary to obtain its antiseptic effect in the system against the supposed disease-ferments.

To carry out the plan of treatment in such cases as follow requires the constant supervision of a medical man or of a very intelligent nurse, as the indications followed in these cases for the administration of the drug hypodermically was the temperature. The preparations used were a "syrup of nascent phenic acid," each half-ounce representing 2½ grains of the acid. A "syrup of ammonia-phenate," each half ounce containing 2½ grains of the ammonia-phenate. Hypodermic solutions of the nascent acid and of the ammonia-phenate, each of the strength of 2 grains to 100 minims. Also "glycophenique," a ten per cent solution in glycerine.

The injections were given warm and introduced into the subcutaneous cellular tissue. When this detail was observed, no inconvenience followed in any instance. On a few occasions attendants, unfamiliar with this point, gave the injections and abscesses resulted.

Case I.—*Compound fracture of leg—Amputation—Pyæmia—Recovery.*—Pietro D'Astee, aged twenty-five; Italy; laborer. Admitted December 12, 1881, to Ward 9. Patient was brought to city by train from Haverstraw, where he was employed, working as a laborer on the railroad. An embankment had given way, and he had been struck on the right leg by a heavy mass of falling stones and earth.

Examination.—Both tibia and fibula were fractured about 2½ inches above the ankle (right leg). A large lacerated wound situated on the outer side of the limb communicated with the site of fracture. There was some comminution, but the fragments were not displaced nor loose. The wound was rendered as aseptic as possible; drainage-tubes were inserted in such a manner as to insure evacuation of all discharge, and a full Lister dressing was applied. The limb was then placed in a fracture-box.

December 14th.—Temperature, 101°. Discharge has come through. Dressing was renewed. Wound looks well. There is a large contused surface on inner side of leg, which looks as if it were going to break down and leave a large slough.

December 20th.—Since last account there have been variations of temperature from 100° to 104°. There is no reaction in the wound. A large slough has formed on the inner side. The foot is very œdematous and discolored. Several of the fragments have become loose and were removed. Frequent dressing, quinine, etc., do not control the temperature nor improve the condition of the patient. Pulse, 140, feeble and compressible. Sordes over teeth and lips. Has had considerable diarrhœa and profuse sweats. Lister is abandoned and open treatment resorted to, the wound being washed out with Bals. Peruv. four or five times daily.

December 24th.—Condition of the patient worse. The wound is one large slough. No reaction. Foot more swollen and discolored. Patient had a marked chill this A.M. Range of temperature from 99½° to 104½°. Appearance of bed-sore over sacrum.

December 26th.—Leg amputated by Dr. Hartley. Open treatment resorted to. Transferred patient to Sturgis' Pavilion.

[The chart notes taken hourly from the day of amputation, December 26, 1881, to January 10, 1882, when the phenic acid treatment was instituted, give an unmistakable picture of pyæmia. The temperature averaged 102½° to 103° F., the highest noted being 105½° F., with two or three remissions. Once it was noted to be subnormal. In spite of the use of quinine, full diet, and the most vigorous stimulation, the condition became progressively worse. The history continues.]

January 10th.—Since last account symptoms have rapidly increased in severity. Patient had a marked chill on the 2d inst., also on the 5th, and a less distinct one on the 10th. Pulse is very feeble and rapid, despite active stimulation; countenance is anxious; teeth and lips covered with sordes; tongue brown and dry; stupor and muttering delirium are present. The stump is dry; no signs of granulations. Has had diarrhœa at intervals. The skin is of a dingy, yellow hue. The bed-sore over the sacrum is very extensive, and covered with large, deep sloughs. Other sores have appeared over the crest of the ilium and trochanter on the left side. The patient has exhaustive sweats. It was decided on January 11th to transfer the case to a *medical* ward, the symptoms, according to Dr. Weir's opinion, pointing unmistakably to pyæmia. A fatal prognosis is given by Dr. Weir and confirmed by Dr. James R. Wood, who was called in consultation.

January 11th, 6 P.M.—Patient put under full Déclat treatment. Ordered 100 gtt. ammon. phenat., hypodermically, q. 4 hr.; Syrup ammon. phenat.,

[1] Read before the New York Surgical Society, May 9, 1882.

℥ ss. q. 3 hr.; ℥ j. whiskey, q. 1 hr.; Tr. ferri chlorid., 34½ ♏xv. q. 3 hr.; Tr. digitalis, ♏v. q. 4 hr. Stump and bed-sores dressed with olive oil and glyco-phenique, equal parts, q. 12 hr. Ordered urine to be examined q. 12 hr. for sulphates. The hypodermics are to be warmed and injected carefully into the cellular tissue over chest and abdomen.

January 12th.—6 A.M.: Temperature, 103°; pulse, 128°. 12 M.: Temperature, 102°; pulse, 130°. 6 P.M.: Temperature, 103°; pulse, 110°. Same orders have been carried out. An extra injection was given during the morning and in the evening.

January 13th.—1 A.M.: Temperature, 99°; pulse, 120°. 11 A.M.: Temperature, 98¼°. Same orders repeated. There is no change in the condition of the patient. The stump and bed-sores have not improved in appearance. The pulse is yet rapid, but somewhat firmer. 4 P.M.: Temperature, 100°. 6 P.M.: Temperature, 100¼°. 9 P.M.: Temperature, 100¼°. Pulse, 9 P.M.: 104°.

January 14th.—1 A.M.: Temperature, 102°. Hypodermics to be given q. 2 hrs. till further orders. 6 A.M.: Temperature, 100¼°. 10 A.M.: Temperature, 101°.

The patient is stupid. No change in the condition of the wounds. Seems to experience some pain over points where injections have been given. Pulse, 130, and very feeble. No chill. Profuse sweats. Hypodermics continued, q. 2 hr. Other orders repeated. 6 P.M.: Temperature, 100°.

January 15th.—6 A.M.: Temperature, 101°. Same orders carried out. No improvement, except that the pulse is stronger (100). 6 P.M.: Temperature, 100°; 11 P.M., 100½°.

January 16th.—5 A.M.: Temperature, 99½°; 12 M., 100°; 6 P.M., 99½°. This P.M. sulphates are absent from urine, which is quite dark in color. Hypodermics to be given q. 4 hr. only. Other orders repeated.

January 17th.—5 A.M.: Temperature, 99½°; pulse, 112. 12 M.: Temperature, 100°. 6 P.M.: Temperature, 100°; pulse, 100. The pulse is stronger. Patient seems to be delirious still. Has one normal passage, copious, every A.M. Sulphates are still absent.

January 18th.—1 A.M.: Temperature, 99½°; 12 M., 99°. Sulphates have reappeared. Tongue is less coated than six days ago. Sweats less profuse. No change in the appearance of wounds, except that the sloughs over sore of the sacrum are clearing. 6 P.M.: Temperature, 99½°.

January 19th.—6 A.M.: Temperature, 99°. 10 A.M.: Temperature, 100½°; pulse, 100. The patient is less stupid. There is some discharge from the stump. Pulse still feeble. Orders the same. 11 P.M.: Temperature, 100°.

January 20th.—3 A.M.: Temperature, 99½°; 6 A.M., 99½°; 8 P.M., 100°; 11 P.M., 101°. Hypodermics to be given q. 3 hr. Syrup, whiskey, iron, and digitalis as before.

January 21st.—6 A.M.: Temperature, 99°; 10 A.M., 100°; 6 P.M., 100°. Hypodermics have been given only q. 4 hr. since morning.

January 25th.—Since last account temperature has been continuously between 99° and 100°; pulse between 100 and 120. The sordes are disappearing. There is considerable discharge from the stump, where granulations are appearing. The bed-sores are free of sloughs. Digitalis is discontinued. Hypodermics given q. 4 hr. Syrup ammon. phenate, q. 4 hr. Whiskey and ferri chlorid. as before.

February 1st.—It is considered safe for the patient to return to a surgical ward. The bed-sores are beginning to heal; the stump is granulating; the tongue is pink and moist. Pulse between 80 and 100; regular and quite strong. The glyco-phenique is replaced by iodoform dressings. Hypodermic ac. ph. to be given q. 6 hr. Syrup ammon. phenate, ℥ ss. q. 6 hr.; whiskey, ℥ j. q. 2 hr.; tr. ferri chlorid., ♏. xv. t. i. d.

February 6th.—Injections are discontinued. Syrup continued.

At the present time the patient's condition is as follows: Stump healed; bed-sore upon the sacrum, which was twice as large as the palm of the hand, now about the size of a dollar. Appetite excellent, not to say voracious. Has been sitting up daily for some time. One afternoon, about two weeks since, the patient was noticed to be ill. He speaks no English, and made no complaint. He seemed dull, and his temperature was 104°. His urine was found to contain an abundance of albumen. This had never before been detected. The next day the fever had disappeared, and the patient returned to his usual condition. With the exception of the continued presence of albumen in the urine, although in somewhat diminished quantity, the favorable progress of the patient seems to have not been interrupted. Whether the albuminuria has any connection with the previous treatment is not known. During the time it was carried out no albumen was found.

Two points are worth noting in this case. First, the rescue of the patient from what seemed impending death from pyæmia. Secondly, the amount of phenic acid tolerated. From the morning of January 14th until the evening of January 16th—two and one-half days—he received hypodermically 2 grains of ammonia-phenate every two hours, or 24 grains per diem. In addition, he took by mouth, in the syrup, 22.4 grains per diem, or 46½ grains per diem in all. At the end of these two and a half days the urine gave warning of approaching toxic symptoms, and the dosing was diminished.

CASE II.—*Compound fracture of tibia, and simple fracture of tarsus—Delirium tremens—Death.*—Frank Martin, 13 Madison Street; single; aged twenty-two; Ireland; driver. Admitted to Ward 9, April 3, 1882. At the time of admission patient was intoxicated. Afterward he stated that he had been on a spree; also that he was in the habit of drinking steadily. Apart from his alcoholism the general condition of patient was good. His urine was normal.

Examination.—There is found to be a fracture of the left tibia at about the junction of the middle and lower thirds of its shaft. The line of fracture is very transverse, and there is no comminution. On the upper and inner aspect of the leg is a wound that leads down to the point of fracture. The wound in the skin is rather clean cut, but the deeper tissues are a good deal lacerated. There is a great deal of swelling around the right ankle, which renders the diagnosis rather obscure. On some motions, deep-seated crepitus can be elicited, and a fracture of one of the bones of the tarsus is considered probable. There is doubtless some synovitis at the ankle, giving rise to swelling, fluctuation, and very intense pain and tenderness. The patient was injured by falling from the front platform of a street car; the wheel of the car passing over his right foot and left leg.

Treatment.—The left leg and wound in same were thoroughly washed with a five per cent. solution of carbolic acid, the fragments put in good position, and the leg put up in a Lister dressing, and placed in a fracture-box, a drainage-tube having been in-

serted in the wound. *The right leg* was put in a fracture box, and hot lead and opium wash kept over the ankle. Patient was ordered whiskey, ʒ ss. q. 3 hr., and potassi. bromide, ʒ j.

April 4th.—To-day patient having come out of his intoxication, feels very well. His leg was dressed this A.M., and it is looking healthy. There is swelling, and the bones are in good position. Temperature, 100½°. No cause for the pyrexia can be found in the compound fracture. Patient ordered a dose of salts to move his bowels.

April 5th.—Patient's condition remains about the same. His temperature continues high. To-day it is 102°. His right ankle is more swollen and painful. It is thought that patient's high temperature may be due to the synovitis. An apparatus was arranged which keeps a stream of cold water continually playing over his right ankle. About an hour after this was applied his temperature fell to 100½°, being one and one-half degree lower. It did not, however, remain down long, and by 4 P.M. his temperature reached 103°. His leg was dressed, but the temperature, instead of falling, rose higher.

April 6th.—This A.M. patient's temperature was 103°, having been higher during the night. He has had large doses given him of quiniæ, but these have failed to reduce temperature. As yet he seems to feel quite well, and does not complain of any particular pain, except in his right foot. This afternoon his leg was dressed, and a slight prominence was found on the upper aspect of the leg opposite the site of fracture. A hypodermic needle was introduced, and a small quantity of ichorous fluid was drawn off, which proved to be bloody serum, containing a very few pus-cells. At 6 P.M. his temperature was 104½°. Patient was ordered 100 minims of phenic acid, q. 4 hr.; whiskey, ʒ ss. q. 2 hr.

April 7th.—Patient's temperature is still high, not having been below 104° since yesterday P.M. His leg was dressed this P.M., and more drainage made. One tube was put in a sinus which ran down on the inner side of the leg, and was brought out through a counter-opening pretty well underneath. The second tube was carried from the upper part of the leg downward and outward, so as to drain the small cavity which was aspirated yesterday. The patient was very restless and excitable in the latter part of the day, and became by midnight quite delirious.

April 8th.—Temperature this A.M. was down to 101½°, but it soon rose again, and at noon was 103°. Patient's delirium still continues, and during evening he becomes so violent that he has to be tied in bed. Ordered bromide potassii, large doses.

April 9th.—Temperature this A.M., 103¾°. He is still given 100 minims acide phenique, q. 4 hr. His delirium has changed in its character, and now is confined to general mutterings, though occasionally he becomes violent as before. His leg was dressed this P.M., and the appearance of it was found about the same. It drains perfectly and looks well. The siphon, which had been playing cold water on his right foot, was stopped to-day, and the foot was placed in a fracture-box.

April 10th.—This morning the patient's temperature had fallen to 102°, and at noon was down to 100½°. His muttering delirium continued, and he seemed to be a good deal weaker than on yesterday. His stimulants have been increased to ʒ ss. every hour. A small spot of consolidation was discovered this morning in the apex of his right lung. No ralês could be heard. There is some dulness and an indistinct bronchial respiration.

April 11th.—Temperature since yesterday has remained low. It reached 102° at midnight, but has not been above that point, and at 6 A.M. to-day it was 101¼°. It continued low till 9 P.M., when it suddenly rose to 105½°. The patient has become very much weaker and has pulmonary œdema.

April 12th.—The patient died at 5.30 this A.M., with a very weak heart and pulmonary œdema. No autopsy could be obtained.

The next case is one of erysipelas, in which, on one day, at least (January 25th), the fall of temperature seemed due to the use of phenic acid. A similar apparent effect may be noted in Case IV., on January 15th.

CASE III.—*Erysipelas—Recovery.*—John Munns, aged fifty-five; England; clerk. Admitted January 23, 1882. On night of 22d had chill, vomiting, fever, and swelling of face. At 4 P.M., January 23d, he felt so ill that he decided to come to hospital. 6 P.M.: Temperature, 104°. Given hypo. ammon. phenat., 100 gtt. Ordered syrup ammon. phenat., ʒ ss. q. 3 hr.; also whiskey, ʒ ss. q. 3 hr. 11 P.M.: Temperature, 103½°; hyp. ammon. phenat., 100 gtt., as before.

January 24th.—3 A.M.: Temperature, 101¼°; hyp. as before. 7 A.M.: Temperature, 101°; hyp. as before. 10 A.M.: Temperature, 102½°; hyp. as before; syrup and whiskey continued as before. 3 P.M.: Temperature, 102¼°; hyp. am. ph., 100 gtt. 6 P.M.: Temperature, 103°; hyp. am. ph., 100 gtt. Face was painted on admission with tr. benzoin co., and a mask of sheet lint wet in lead and opium wash was applied. 10 P.M.: Temperature, 101¼°; hyp. as before.

January 25th.—2 A.M.: Temperature, 101°; hyp. as before. 6 A.M.: Temperature, 99°; hyp. as before. 10 A.M.: Temperature, 99°; hyp. as before. Syrup as before; whiskey increased to ʒ ss. q. 2 hr. Pulse, 120, and rather feeble. The patient's face, neck, and scalp are enormously swollen and very painful. 2 P.M.: Temperature, 104°; hyp. as before. 4 P.M.: Temperature, 102½°; hyp. as before. 6 P.M.: Temperature, 100°; hyp. as before. 10 P.M.: Temperature, 101°; hyp. as before. Ordered bromide (1-4) ʒ ii. q. 4 hr. Patient is restless, but not delirious. Complains of some soreness at the point where injections were given.

January 26th.—2 A.M.: Temperature, 101°; hyp. ac. ph., 100 gtt. 6 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 99¾°; hyp. ac. ph., 100 gtt. The swelling is beginning to abate. The patient complains less of pain. Scalp is still very œdematous and tender. Pulse, 106. Weak. Whiskey and syrup continued as before. 2 P.M.: Temperature, 102°; hyp. ac. ph., 100 gtt. 6 P.M.: Temperature, 101°; hyp. ac. ph., 100 gtt. 10 P.M.: Temperature, 99°; hyp. ac. ph., 100 gtt.

January 27th.—2 A.M.: Temperature, 100°; hyp. ac. ph., 100 gtt. 6 A.M.: Temperature, 98¼°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. Patient feels quite comfortable. Pains have disappeared from face, neck, and scalp. Swelling and redness are detected with difficulty. 12 M.: Temperature, 99½°. 4 P.M.: Temperature, 100°; hyp. ac. ph., 100 gtt. 8 P.M.: Temperature, 99°; hyp. ac. ph., 100 gtt.

January 28th.—1 A.M.: Temperature, 98¼°; hyp. ac. ph., 100 gtt. 6 A.M.: Temperature, 98½°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 98¼°; hyp. ac. ph., 100 gtt. The swelling has completely disappeared.

Patient says that he feels perfectly comfortable, although weak. 2 P.M.: Temperature 99°; hyp. ac. ph., 100 gtt. Syr. ac. ph. ordered, ʒ ss. q. 4 hr.; whiskey, ʒ ss. q. 3 hr. Patient has a small fluctuating tumor on left thigh, at a point where a deep injection of 100 gtt. phenate of ammonia was given. No heat nor redness. An aspirator needle introduced, and about ʒ ii. pus withdrawn. 6 P. M.: Temperature, 98½°; hyp. ac. ph., 100 gtt.

January 29th.—10 A.M.: Temperature, 98½°. Hypodermics are discontinued. Whiskey and syrup as before.

February 3d.—Temperature has been normal since last account. There has been no further trouble from the abscess in the thigh. There remain one or two spots of induration over the abdomen; but they are not painful and are rapidly disappearing. Syrup discontinued. Ordered quinine sulph. gr.v., t. i. d. Ordered whiskey, ʒ iv. q. 24 hr. During treatment, usual examination of urine was resorted to q. 4 hr. Sulphates never absent

February 5th.—Patient discharged, cured.

CASE IV.—*Erysipelas.*—W. H. Lonsberg; aged forty-five; U. S.; clerk. Admitted January 13, 1882. Patient says that two days previous to admission, he had vomiting. The next day he suffered from chilly sensations and some burning of the face. On morning of the 13th his face was red and swollen, and his eyelids œdematous and almost closed. He decided to come to hospital. 5 P.M.: His face is swollen and red, the œdema extending to the scalp. Temperature, 101°; pulse, 121. Hypodermic injection ac. phenique (2½%) of 100 gtt. Ordered syrup ac. phenique, ʒ ss. q. 3 hr.; also whiskey, ʒ ss. q. 3 hr. Face painted with tr. benzoin co., and a mask wet in lead and opium wash applied. 7 P.M.: Temperature, 102°; 10 P.M., 102½°; hypo. injec. of ac. ph. (2½%), 100 gtt.; syrup to be given at 11 P.M. and 1 A.M. Immediately after injection patient complains of feeling of dizziness and nausea, which passes away, however, in about one minute.

January 14th.—1 A.M.: Temperature, 101¼°; 6 A.M., 99°; 10 A.M., 101¼°; 100 gtt. ac. pheniq., hypodermically; same orders for syrup and whiskey as before. 12 M.: Temperature, 101¼°; 1.30 P.M., 102¼°; 3.30 P.M., 103°. 4 P.M.: Hyp. inject. of ac. ph., 100 gtt. 6 P.M.: Temperature, 102½°; 12 P.M., 103°.

January 15th.—6 A.M.: Temperature, 102¾°; hyp. injec. ac. ph., 100 gtt. 12 M.: Temperature, 101½°. 2 P.M.: Temperature, 103°; hyp. injec. of ac. ph., 100 gtt. Syr. ammonia phenat. is substituted for the syrup of ac. phenique. Whiskey, ʒ ss. q. 3 hr. The swelling and redness of the face are disappearing. Patient complains of some soreness at the point where hypodermics have been given. A certain amount of induration is detected, but no heat or redness. 6 P.M.: Temperature, 102½°; hyp. ac. ph., 100 gtt. 10 P.M.: Temperature, 103½°; hyp. ac. ph., 100 gtt. 12 P.M.: Temperature, 100¼°.

January 16th.—2 A.M.: Temperature, 100°; hyp. ac. ph., 100 gtt. 6 A.M.: Temperature, 99½°; 10 A.M., 98½°. The blush and swelling have completely disappeared. Patient complains of no pain, except at the point where injections were made. 2 P.M.: Temperature, 100½°; hyp. ac. ph., 100 gtt. Whiskey and syrup continued as before. 4 P.M.: Temperature, 101°; 5 P.M., 100½°; hyp. ac. ph., 100 gtt. 9 P.M.: Hyp. ac. ph., 100 gtt.

January 17th.—1 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 98½°; hyp. ac. ph., 100 gtt. Lead and opium applied to points of tenderness where injections had been made. Whiskey and syrup as before. 3 P.M.: Temperature, 100¼°; hyp. ac. ph., 100 gtt. 9 P.M.: Temperature, 99°; hyp. ac. ph., 100 gtt.

January 18th.—1 A.M.: Temperature, 98½°; hyp. ac. ph., 100 gtt. 5 A.M.: Temperature, 98¼°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 101°; hyp. ac. ph., 100 gtt. Pain in abdomen is disappearing. Patient complains of throbbing pain in head. Scalp œdematous. Whiskey and syrup as before. 5 P.M.: Temperature, 104°; hyp. of phenat. of ammonia, 100 gtt. 8 P.M.: Temperature, 100°; hyp. of phenat. of ammonia, 100 gtt. 10 P.M.: Hyp. of phenat. of ammon., 100 gtt.

January 19.—1 A.M.: Temperature, 99°; hyp. acide phenique, 100 gtt. 5 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. Whiskey and syrup as before. No more hypodermics are given. 3 P.M.: Temperature, 100°; 8 P.M., 99°

January 20th.—1 A.M.: Temperature, 98½°; 10 A.M., 98½°. Syr., ʒ ss. t. i. d. Whiskey, ʒ i. t. i. d.

January 24th.—Since last account temperature has been normal. Syrup discontinued. The pain over points of injections has disappeared. During ac. ph. treatment, urine was examined q. 12 hr. with barium chloride and nitric ac. test. Sulphates always abundant. Patient discharged, cured.

CASE V.—*Erysipelas of wound—Normal temperature in two days.*—John Hargent, aged fifty-two; England; 'longshoreman. Transferred from Ward 9, January 18, 1882. The patient was admitted to Ward 9, January 16, 1882, suffering from fracture of the nose and lacerated wounds of face. Erysipelas developed, and he was transferred to pavilion.

January 18th.—10.40 A.M.: Temperature, 101° F.; pulse, 100. 12 M.: Given hyp. injec. ac. ph., 100 gtt. Ordered syrup ac. phenique, ʒ ss. q. 3 hr.; also whiskey, ʒ ss. q. 3 hr. A light dressing soaked in glyco-phenique, one part, to olive oil, three parts, placed over wounds. 5 P.M.: Temperature, 102°; hyp. ac. ph., 100 gtt. 8.30 P.M.: Temperature, 101¼°; hyp. ac. ph., 100 gtt.

January 19th.—1 A.M.: Temperature, 100¾°; hyp. ac. ph., 100 gtt. 5 A.M.: Temperature, 100¼°; hyp. ac. ph., 100 gtt. 10 A.M.: Temperature, 100°; hyp. ac. ph., 100 gtt. Syrup and whiskey continued as before. Same dressing continued as before. 3 P.M.: Temperature, 99¼°; hyp. ac. ph., 100 gtt. 8 P.M.: Temperature, 100°; hyp. ac. ph., 100 gtt. 12 P.M.: Temperature, 98¾°; hyp. ac. ph., 100 gtt.

January 20th.—4 A.M.: Temperature, 99°; hyp. ac. ph., 100 gtt. 9 A.M.: Temperature, 98½°; hyp. ac. ph., 100 gtt. The blush and swelling have completely disappeared. Patient states that he feels perfectly well. Hypodermics discontinued. Ordered syr. ac. ph., ʒ ss. q. 4 hr.; also whiskey, ʒ ss. q. 4 hr.

January 24th.—Since last account temperature has been normal. No pain. Syr. discontinued. Ordered quiniæ sulph. gr. v. t. i. d.; whiskey, ʒ iii. q. 24 hr. Wound is granulating nicely.

January 30th.—Wound has completely healed. Fragment of nasal bones in position; good union. During treatment urine was tested for sulphates without result. Patient discharged cured.

The relation in these latter cases between the use of the acid and the fall of temperature is not as evident as it might be. Dr. Magnin believes that these cases were, nevertheless, of shorter duration than other cases of the same degree of severity, under

other plans of treatment, at the same time with the same surroundings.

I submit these cases for what they are worth, feeling that any plan of treatment which claims to help us out of the desperate straits in which septic accidents place us, is deserving of a hearing.

THE HISTORY OF A UNIQUE CASE ILLUSTRATING SOME VASO-MOTOR DISTURBANCES.

By BEDFORD BROWN, M.D.,
ALEXANDRIA, VA.

George C——, originally a vigorous, muscular man, about forty-five years of age, had for several years past been engaged in the occupation of a professional diver in the employment of the Government, and, at the time he became disabled, was on the coast of North Carolina.

While pursuing his vocation of diver, he was accustomed to wear a peculiarly constructed diving apparatus, with an enormous weight fitting to the back and pressing on the lumbar region firmly. Some two years since he detected over that region a slight prominence, extending about four inches in length, and probably two inches in breadth, and projecting out from the spinous processes of the lumbar vertebræ a half inch. The prominence was very firm and unyielding, and with but little tenderness on pressure, but occasionally the seat of sharp and severe pains. To all appearance it involved the cellular tissue and structures in the vicinity of the spinal column.

The enlargement increased gradually, and at certain periods, gave more pain, until he came under my professional charge. Notwithstanding the increasing inconvenience, he continued to pursue his calling until prostrated by a severe attack of malarial fever on the coast of Carolina, in September last.

He returned to his home in this city, while suffering from this attack. He then had fever of a remittent type, jaundice, constipation, delirium, paralysis of the bladder, excruciating pain over the affected lumbar region, extending down the left limb, scanty and alkaline urine.

At this time the prominence over the lumbar region projected at least an inch and a half above the level of the spinous processes. It was very hard, firmly attached to the surrounding structures, but not sensitive to pressure. It had all the indurated character of cartilage, but not the hardness of osseous material.

After the malarial symptoms had been completely subdued by treatment, there began to appear a remarkable series of morbid phenomena, chiefly of nervous character.

In this case there was not the remotest indication of spinal curvature, or disease of the osseous structures of the vertebræ.

Nervous phenomena.—For some two or three weeks after the subsidence of fever, the lumbar region continued to be the seat of excruciating pain.

Then the nerves of the left leg, the sciatic, crural, and all their principal branches extending down to the heel and toes, became affected with the most intensely agonizing form of neuralgia, but partaking rather of a paroxysmal character.

Associated with this neuralgia there existed well-marked anæsthesia of skin of the thigh and a portion of the left leg. When the hypodermic needle was introduced in these localities the patient was always oblivious of its entrance without his attention was called to it. Paroxysms of clonic contraction of the flexor muscles of the toes were now of frequent occurrence, often lasting for hours. These were entirely beyond the control of the patient, and were evidently not reflex in character, but central in origin. The diaphragmatic muscles also participated in this tendency to clonic spasm to a moderate extent.

This was manifested by a sense of constriction and tension in the region of the diaphragm, accompanied with neuralgic pains. At a later stage of the case, some three months after the patient came under my charge, the muscles of the left side of the face and eye also became subject to frequent involuntary contractile action, inducing twitching of the eyelid and facial muscles. This was soon followed by complete ptosis of the lid of the left eye, excessive dilatation of the pupil, and loss of vision of that eye. In the midst of all the other troubles, the mental faculties of the patient were not left entirely unimpaired. The memory not only became defective, but the power of reasoning by combination was in a measure seriously impaired.

The paralytic indications in this case were entirely confined to the bladder and eyelid. They were of a comparatively transient character. Both disappeared under treatment. The local anæsthesia was more permanent, lasting for many months.

Phenomena of local temperature in the affected limb —Local fever.—The temperature of the entire limb, excepting the sole of the foot, passed through two regular diurnal changes or rhythms, every morning and evening. These changes would occur regardless of the state of the general corporeal temperature.

For instance, the temperature of the left leg as evening approached would rise to 101° or 102°, while that of the body at large, and the corresponding leg, would stand at the normal rate. This fact was clearly appreciated both by patient and attendants. Thus as night approached the left limb would begin to manifest an increasing temperature. This would continue to increase until nine or ten o'clock P.M., at which period a genuine standard of fever heat would be reached, while the rest of the body would be normal. After this time there would be a gradual subsidence of heat until the normal rate was touched. These peculiar changes of temperature constituted a regular evening febrile exacerbation, confined strictly to a localized section of the body, and presenting a true type of local fever without inflammatory action. During these daily exacerbations of local fever, there was always a transient increase in the vascularity of the leg. The diseased leg would assume a more decided pinkish complexion than the sound; the action of the larger arteries would become more vigorous, and their pulsations stronger; the veins would become more turgid. All these local symptoms would subside to a partial degree with the periodical decline of temperature.

For many months the patient was subject to occasional and most unexpected paroxysms of general fever, usually, but not always, ushered in by a chill, without other premonitions, and terminating without perspiration. These attacks were always easily controlled by quinine.

Peculiar state of the vascular system and nutrition of the left limb.—While there was a daily increase in the vascularity of the limb during the local rise of temperature, and a partial reduction during the cor-

responding decline, there was manifestly a permanent dilatation of the arterioles of the leg.

The right leg and foot were always pale, and presented a perfectly normal state; the left foot and leg a more pinkish complexion, more fulness of the vessels, and a greater degree of warmth.

About the middle of last January, and after the patient had suffered fearful agony for many weeks, principally in the left heel, the skin over the plantar aspect of the part became livid. Soon the cuticle separated from the cutis and was much distended with a dark-colored serum. When the cuticle was entirely removed, the cutis being exposed presented a dark livid color, and was insensible to the touch. Within a few days a faint line of demarcation began to appear in a circular form around this discolored skin, corresponding to the surface of the heel.

The process of separation by sloughing progressed steadily and rapidly until the entire skin and cellular tissue of the plantar aspect of the left heel had become detached and thrown off, leaving a rather livid, unhealthy excavation behind.

Within three days copious granulations began to spring up over the entire excavation.

The cavity was soon filled with exuberant granulations, and within ten or twelve days their rapid growth had projected beyond the surface of the surrounding skin three-fourths of an inch, forming a well-defined, reddish fungus, which spread in all directions in regular umbrella shape. The growth at this stage appeared to have reached its full development, the process of proliferation came to a stand, and that of healing and gradual closing up of the sound skin took place. The fungus had entirely disappeared by absorption, the skin finally healing over perfectly, leaving a well-defined cicatrix. During this process the patient was certainly more than usually exempt from pain.

Throughout the early stages of this growth there was a constant and free discharge of a pure, odorless, transparent, gelatinous substance, amounting to such quantity as to saturate many cloths, and even the bedding, during the day. During the healing stage the discharge was simply purulent. Some three weeks after the subsidence of these peculiar symptoms, a somewhat similar change took place over the ball of the foot, without any indication of sloughing, as in the first instance. Granulations formed, but to a limited extent, and after a continuance of the gelatinous, followed by the purulent discharge, the diseased skin healed perfectly, leaving a rather livid cicatrix.

Notwithstanding the complete healing of these local affections, severe neuralgic pains with evening exacerbations continued in the localities of the cicatrices. A blister, when applied over the peculiar enlargement in the lumbar region, in the process of vesication, caused an effusion, not of serum, but of a gelatinous substance identical with the former examples.

Whether these peculiar exudative phenomena afforded an indication of a morbid condition of the blood, or of the state of that portion of the nervous system which presides over the circulation (the vaso-motor) is a question for consideration.

Certain morbid phenomena in this case, probably due to vaso-motor disease.—Recent experiments of Nussbaum, says Dr. Ringer, if correct, show that in certain animals the vaso-motor centres are not confined to the base of the brain, but that the spinal cord throughout its entire tract is also a centre for the origin of numerous filaments of this class of nerves for distribution to the vascular system. Flint, in his recent work on "Physiology," also says there is abundant evidence of the fact.

Hence there is every reason to believe that disease at the origin of the vaso-motor nerves within the brain or spinal cord is capable of, and does induce an infinite variety of local affections by causing abnormal states of temperature, circulation, nutrition, oxidation, by producing vascular contraction, or spasm, or extreme dilatation, thereby subjecting the particular locality to which the diseased nerves are distributed to sudden changes in temperature and the supply of blood, sometimes by producing vascular dilatation and an excessive supply of blood, thereby inducing increased or overnutrition with hypertrophic tendency; at other times, through vascular spasm cutting off the supply of blood or diminishing it, producing a defective state of nutrition and warmth, with a consequent tendency to atrophy or gangrene. Such I conceive to be the agencies which in this particular case have been in operation for the production of many, if not all of the peculiar local phenomena attending its progress.

We can very readily see how in this way vaso-motor disease may become the cause of those local changes in the vessels constituting active and passive engorgement, rapid cell and tissue proliferation, inflammation, inordinate and abnormal discharges, and gangrene. And we may also readily see how it may become responsible for many abnormal growths, and probably for many of those intractable affections of the skin, compound in their nature, and made up of engorgements of cutaneous vessels, inflammation, and adventitious deposition.

Treatment.—After a complete subjugation of the malarial symptoms, minute doses of oil of turpentine, tinct. of cantharides, and tinct. of nux vomica were used for the paralysis of the bladder, aided by the regular use of the catheter. The patient in a few weeks' time recovered from this. For the intense pain in the back, leg, and foot, every form of opiate, internally and hypodermically, was resorted to, but, of course, with only transient relief. The most permanent in its effects of all these remedies was the compound preparation known as chlorodyne. This agreed well with his digestive powers and general condition. For the absorption and reduction of the lumbar enlargement, blistering, large doses of iodide of potassium, and the steady use of quinine were found the most useful.

I was inclined at first to attribute this enlargement in part to periostitis involving the surrounding structures of syphilitic origin. But the patient, who was a man of moral habits, assured me that he was free of all taint. There was no evidence whatever, either secondary or tertiary, of constitutional syphilis.

At the present time, some six or seven months having elapsed since his recovery from malarial fever, the patient has greatly improved. The lumbar enlargement has almost entirely disappeared. He has recovered vision in the affected eye, and from ptosis of the lid. He has greatly increased in flesh, strength, and appetite.

He can, with the aid of a crutch, walk many squares. But he still suffers from his evening pain in the heel and foot, but in a modified degree, and slight evening rise of temperature in the extremity preceding the pain. I neglected to mention that electricity and minute doses of strychnia had been used, but only to increase the pain.

ON THE REMEDIAL VIRTUES OF TONGA.

By DAVID L. WALLACE, M.D.,

NEWARK, N. J.

This drug, which for years has been used by the natives of the Fiji Islands under the name of "Neuralgia Medicine," was brought to the notice of the profession in March, 1880, by Drs. Ringer and Murrell in a paper published in the London *Lancet*, the remedy having been handed to them by a gentleman named Mr. Ryer, residing in Fiji, with the wish that they should test its virtues.

As used in Fiji, it consists of a loose bundle containing leaves, bark, and woody fibre, the covering consisting of the inner bark of the cocoanut tree. This bundle is steeped in water for twenty minutes, after which the liquid is pressed out, and of this from an ounce to an ounce and a half is taken three times a day before eating. By drying the bundle and hanging it up in a dry place to prevent its getting mouldy, it will answer for a year.

The medicinal virtues appear to reside in the bark and fibre, the leaves apparently being added to deceive persons as regards these virtues.

We have three preparations of the drug—an infusion, watery extract, and alcoholic extract, the last appearing to be the most reliable.

Its action appears to be confined to the nerves of sensation, it having been used with very good effect in controlling pain in diseases of the brain and kidneys. It has also been used topically in certain diseases of the eye, Dr. Bader, ophthalmic surgeon to Guy's Hospital, speaking very highly of it in asthenopia, rheumatic iritis, and diminished tension of the eyeball. Its most brilliant results, however, have been seen in neuralgia, especially that variety attacking the cranial nerves, Dr. Ringer's and many other published cases recording this fact. I have within the past five months used it in quite a number of cases of cephalalgia, and in most of them with uniform good results. In a few istances I have met with failures, but what drug is there that will not disappoint at times?

Of two cases of trifacial neuralgia in which I prescribed it I wish to give a brief synopsis.

Case I.—Miss A. M. L——, aged forty. General health fair. For the past five years, about once a month has had an attack of the supra-orbital variety of both sides, lasting about two days, the pain being intense, and which nothing seemed to control. I saw her for the first time about six weeks ago. The paroxysm at that time was very severe, accompanied with marked intolerance of light and redness of the eye, with an abundant secretion of tears. I prescribed half-drachm doses of the fld. ext. of tonga every two hours. I called again in eight hours and found the pain had disappeared, all that remained being a sense of soreness quite common after these attacks. The relief came, she said, about twenty minutes after the first dose, and three doses accomplished the result as above. Another attack came on about a week ago, and the medicine was prescribed as before, and with the same results. Here we have a patient who, though she may not be cured in the proper acceptation of the term, has a remedy to control the attacks which heretofore have lasted so long and been so exceedingly painful.

Case II.—Mr. E. R——, aged thirty-five; occupation, dry goods salesman. Has been a sufferer from neuralgia of the infra-maxillary nerve for about four years. Came under my notice about six months ago. His attacks were very severe, and lasted invariably from a day and a half to two days. At that time I prescribed internally morphia in quarter-grain doses every three hours, and externally an ointment as follows:

℞.	Veratria	gr. iv.
	Morphia	gr. vi.
	W. aconit rad.	ʒ iss.
	Vaseline	ʒ i.

To be applied to painful part every fifteen minutes. As long as the opiate was continued and the ointment applied he had partial relief, but as soon as their effects began to wear away the pain returned. His attacks lasted two days, during which time it was necessary to keep up the medicines. He sent for me about three weeks ago for the same trouble, at which time I prescribed half-drachm doses of the fld. ext. of tonga every hour. The result was exceedingly satisfactory, the pain being controlled by the first dose and disappearing entirely after the fourth.

My experience with tonga has been remarkably good, and I think this drug, so highly useful in cases of neuralgia, and one which can be given without producing toxic effects—a claim that cannot be advanced for other medicines heretofore used in this complaint—deserves a place among our successful new remedies.

A UNIQUE CASE OF FOREIGN BODIES IN THE GASTRO-INTESTINAL CANAL—EVACUATION PER ANUM.

By SAMUEL KOHN,

NEW YORK.

To collect the reported cases of foreign bodies which have traversed the gastro-intestinal canal, and have been evacuated per anum, would require the ransacking of the files of nearly every medical journal for the last third of a century, since no bibliography of this subject has, to my knowledge, yet appeared.

A perusal of those journals which are accessible convinced the writer that the case about to be reported is an *unicum*. The history, briefly, is as follows: Mrs. J. G——, suffering from melancholia, with intercurrent attacks of mania, was, at the request of her parents, removed from the asylum to her home in this city. Symptoms which had manifested themselves during the last days of her stay in the asylum, now appeared in a graver form. Green-paint vomit, constipation, small, rapid pulse—120 per minute—a temperature of 102½° F., a pale, anxious countenance, were the general symptoms. Locally: Generalized abdominal pain, with special sensitiveness in the right iliac region; meteorism moderate; tongue thickly coated. The patient was very reticent, only saying and reiterating that she was "rotten inside," and could not possibly live. The diagnosis of peritonitis, localized in the right iliac region, appeared the proper one. After three days the constipation gave place to a mild form of diarrhœa, and all the urgent symptoms disappeared. Temperature and pulse fell, not to the normal, however. Vomiting was the only persistent symptom, but not as severe as at the outset; it invariably occurred after partaking of solid food; the patient was therefore supplied only with liquid or semi-solid nourishment.

This lull, after lasting for five days, was inter-

rupted by a second attack of peritonitis (?), presenting the same symptoms and lasting the same length of time as the first one above recorded, to be in turn followed by slight diarrhœa and relief from the distressing symptoms. For five weeks this alternate train of symptoms was observed by the writer; partial intestinal obstruction occurring four times. The treatment consisted in rest—though this was at times difficult, owing to the unmanageableness of the patient—the administration of opiates, etc.

Somewhat after five weeks the mother of the patient came to the writer's office, and said that, in obedience to instructions, she had regularly examined the evacuations, and that she had that morning found in the vessel a long, hard, spindle-shaped mass of fæces, encased in glairy mucus. Examination revealed the edges of several spoons protruding from the mass. Softening and breaking it up, she found it to contain three teaspoons, which she immediately brought to the writer's office. They certainly bore every evidence of their prolonged sojourn in the tortuous canal of the intestine.

On cleansing them with water it was seen that the three spoons must have traversed the canal lying in apposition with each other—the convexities of the one fitting into the concavities of the other, for the reason that the portions exposed to the action of the intestinal fluids and gases were blackened by them, while the protected parts retained the grayish-white color of britannia metal.

After the evacuation of the *materies peccans*, all symptoms of abdominal trouble disappeared, and none have since then returned. Measurements of spoons: Length, 5¼ inches; breadth of bowl, 1¼ inches.

The patient now declares that she swallowed the three spoons in one day, with the intention of thus ending her existence. Had one of them become wedged crosswise in any portion of the intestine, as has occurred in one of the reported cases, her plan would have been crowned with success.

Sexual Perversion.—The disgusting, but from an anthropological, ethnological, and medico-legal point of view important topic of sexual perversion is once more extensively discussed by Krafft-Ebing, to whom we owe the greater part of our scientific knowledge of this subject. It was Casper who first recognized the fact that the inclination of women for women (Lesbian love) and men for men, a perversion afflicting the human race from antiquity, may be of a diseased nature. Westphal questions whether it is always pathological; and Krafft-Ebing believes that this doubt must be carefully weighed. In summing up the observations thus far collected, seventeen in all, the latter author finds that hereditary taint was present in the shape of insanity in the ancestry in thirteen, and in all the cases except one, and in this one case temporarily so, the patients were neurotic and presented positive insane manifestations. Inasmuch as the patients do not as a rule indulge in pæderasty, but abhor it as much as normal and healthy persons, Krafft-Ebing suggests that the enactments against unnatural intercourse specify and should be limited to pæderasty, abuse of persons under fourteen years of age, and of animals. Thus the sufferers from sexual perversion would be able to follow their tendencies to any extent not involving an injury to the rights of others or public scandal.—*Journal of Neurology and Psychiatry.*

Reports of Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

Service of D. HAYES AGNEW, M.D.,

Professor of Surgery.

(Reported by Guy Hinsdale, M.D.)

CHRONIC CYSTITIS.

This patient, for the last ten years, has been suffering from some bladder trouble. He complains now of an increasing frequency in passing urine, and states that in rainy and damp weather this affection is worse, and that he is now called upon to pass his water from eighteen to twenty times in the twenty-four hours. The urine is cloudy, but does not contain blood; it is loaded with mucus and pus, and, on standing, deposits a ropy, gelatinous mass. There is also a prolapse of the rectum induced by straining. The patient suffers from piles and a fissure of the rectum, and this point of irritation, being next to the bladder, excites it to frequent efforts to empty itself. Patients may desire to pass their water very often during the day, but are, perhaps, able to sleep all night without rising.

In the case before us there is not much pain unless he attempts to resist the flow of urine. When he does experience pain, it is situated deep in the perineum and about the neck of the bladder, not at all at the end of the penis. The seat of pain in this class of cases always helps us in recognizing the character of the disease. In inflammation of the prostate gland, the pain is chiefly restricted to the perineum and anus, and is accompanied by a sense of weight and fulness. As disease of the prostate progresses, the pain becomes more acute and radiates from the perineum to the back, the anus, the testicles, along the spermatic cords and down the thighs—wherever, in fact, there are nervous cords communicating with the hypogastric plexus. In cases of stone in the bladder the patient complains of pain felt near the external urinary meatus. Again, in cases of stone the pain is experienced *after* urination. Whereas, in disease of the prostate it exists during the whole act. In cystitis the pain is experienced *before* the bladder is emptied. In prostatitis the pain is aggravated during defecation, but in cystitis it is not necessarily so. Again, in prostatitis, an examination through the rectum reveals marked swelling and tenderness of the prostate, the stream of urine is diminished in size and retention may even occur. In cystitis, however, these conditions are absent. Another question which it is well worth while to ask, is whether, in beginning to urinate, he can start the water quickly, and whether he is not compelled to wait for a certain time before discharging the last few drops. Should you find that this is the case, you may reasonably suspect that you are dealing with a stricture.

Prostatic enlargement is essentially a disease of advanced life; it is rarely seen in subjects under fifty years of age. The muscular fibres and the connective tissue of the prostate body are prone, at this period of life, to undergo excessive nutrition altogether independent of inflammatory changes.

When men of advanced age come to you with the complaint that they are compelled to urinate more frequently, and that increased efforts are necessary

to eject the water, always make an examination through the rectum. We often meet with cases in which this process has been going on for a long time. The encroachment upon the urethra, being associated with impairment of the muscles which are so efficient in promptly emptying the bladder and clearing the urethra, causes the retention of a certain amount of urine. This accumulates until the organ becomes increased in size and, as the distention progresses, the urine begins to dribble away. Such is the true state of affairs in what is so often called "atony of the bladder," a condition the character of which is occasionally unrecognized from the failure of the practitioner to reconcile a constant flow of urine with the idea of retention.

I may say here that nothing is so false as to suppose that every old man has disease of the prostate; even those advanced in life and suffering from bladder trouble are very often free from such enlargement.

I now introduce the sound into this man's urethra and I find no obstruction in its track. There is no stricture. I explore the bladder and I think that we may also eliminate the subject of stone. I will now guard my finger with a little soap and examine through the rectum. I feel the prostate body distinctly and can say that it is not enlarged. The sphincter muscle is totally relaxed. There is, therefore, no stricture, no stone, no enlargement of the prostate. Thus we have narrowed the case down to either one of a growth in the bladder or an ordinary cystitis. Bearing in mind, now that the sound revealed nothing unusual within the cavity of the bladder and that the urine contains no blood, but, on the other hand, is loaded with mucus and pus, we can have no hesitation in saying that it is a case of chronic cystitis.

This disease is one of the most hopeless of all affections. It is more common in men than in women, and may be traced invariably to some pre-existing disorder of the urinary passages. A large number of these chronic cases are beyond the reach of any remedial measures you may adopt.

Acute cystitis is not a very common affection. It may be traumatic in its origin, or may be developed from an extension of inflammation from neighboring parts. I have asked the patient the question whether he ever had an attack of gonorrhœa, but he says that he has not. In acute cases of cystitis from this cause the disease is confined chiefly to the neck of the bladder. The imprudent use of certain drugs, such as cantharides and oil of turpentine, may cause an irritation and congestion of the same region.

Chronic cystitis scarcely ever gets well. For its treatment a great variety of measures have been recommended, proving, by their very number, the difficulties of its cure. In undertaking the care of such a case, endeavor to ascertain, if possible, its cause. If occasioned by stricture, your attention should be directed to its removal; if it arise from stone in the bladder, no progress will be made until that is removed. Local bleeding, which is of great value in acute cystitis, is rarely called for in chronic cases unless an acute condition has been superimposed upon the chronic, when the application of leeches to the perineum will be followed by relief.

The urine should be maintained, as nearly as possible, in a neutral state, and should be closely watched. If you find it acid, you will correct it with alkalies, such as the bicarbonate of soda or liquor potassæ, but when the reaction is alkaline, you will have recourse to nitric or nitro-muriatic acid. When urine is retained and, as a result, its chemical constitution becomes altered, a soft catheter should be employed once or twice a day, if its introduction do not increase the irritability of the bladder. An opium suppository introduced at bedtime into the bowel, may be demanded if the patient be harassed at night. It is important that the patient should endeavor not to obey every call that he has to pass water. He will soon be able to resist, and, instead of using the chamber every half or three-quarters of an hour, he will be able, after a while, to hold his water two or three hours at a time.

Of medicines by the mouth you will find that tar and tar-water, copaiba, turpentine, uva ursi, pareira brava, and benzoic acid are among the most important. Whichever you select, advise your patient to drink plain water freely. If the remedy you choose should fail to afford relief, change it for another, until the one best suited to the case is found. In many cases I have used this formula with great benefit:

℞. Decoct. uvæ ursi..... fl. ʒ viij.
Liquor potassæ..... gtt. cxxx.
Succi belladonnæ..... gtt. xlviij.
M. Sig.—Tablespoonful every four or five hours.

Another drug which I like, and which we will use in this case, is a decoction of triticum repens. You may make it by placing two ounces in a quart of water and boiling to a pint.

The patient should be directed to take the whole pint during the day. This remedy has been long known to have a decided influence in bladder troubles.

Injections into the bladder, either plain or medicated, by washings or by irrigation, are, in my belief, of very doubtful propriety. I am convinced of their bad effects and have for some time abandoned their use.

Opening the neck of the bladder, cystotomy has also been practised for the cure of this disease, the plan being to drain the urine from the bladder as soon as it enters, and, in this way, to remove one of the principal causes of the perpetuation of the trouble. The operation is not an established method of treatment, and its statistics, as they stand at present, are not very flattering.

The diet of your patients must be carefully regulated. So, also, their exercise and habits of life. Stimulating or highly seasoned food, wines and liquors of all kinds, must be avoided. Old cider, however, if perfectly sound and not too acid, may sometimes be drunk with advantage. Innumerable mineral waters have been highly extolled as possessing remarkable powers over these affections, but they have little superiority over good, pure, plain water. The Rockbridge alum and the Vichy waters, however, deserve their good reputation as palliative diluents. Warm clothing, thick shoes, a free action of the skin, and the avoidance of excesses of all kinds, must be enjoined.

If your patient, after all, should fail to improve, and nothing in the whole range of remedies that I have mentioned seems to be of benefit, do not be disheartened at your want of success. These cases, even in the most skilful hands, often prove the most obstinate we have to deal with. And here I want to say one word about the early use of opium —the less you have to do with it, the better. You should always look upon it as the *dernier ressort*.

HOSPITAL FOR DISEASES OF THE THROAT AND CHEST, LONDON.

UNDER THE CARE OF PROSSER JAMES, M.D.

CASES OF SYPHILITIC DISEASE OF THE THROAT.

SOME very interesting cases of syphilitic lesions recently presented themselves at the clinic.

CASE I.—This patient applied, on May 17, 1882, for difficulty of breathing and swallowing. The patient, on a casual glance, appeared to be suffering from acute tonsillitis. On oral examination this diagnosis appeared at first to be confirmed. Both tonsils were enormously enlarged, so much so as to meet in the median line and crush the uvula between them. They were covered with a mucopurulent secretion exhaling a most offensive odor. On looking around the oral cavity Dr. James found what was apparently a mucous patch, and on questioning the patient he acknowledged to contracting primary syphilis three months previously. He was ordered small doses of gray powder. As deglutition was difficult, he was told to place the powders on his tongue, and then swallow them by drinking a small quantity of water slowly. On the 24th inst. he again attended, and stated that he was much better. His countenance had assumed a healthy appearance and his voice was natural. On inspection the tonsils had diminished in size to about half, so that the posterior wall of the pharynx and posterior pillars could now be seen, on which one or two mucous patches appeared. The patches observed on the anterior pillars and on the tonsils the previous week were entirely gone. He was ordered to continue the powders and warned of the danger of neglecting to continue the treatment.

CASE II.—Jonathan B——, aged twenty-four, had been an in-patient, in 1873, for laryngeal affection, which was supposed to depend on hereditary syphilis, and which he had been then (1873) suffering from for a period of five years. The symptoms in 1873 were so urgent that tracheotomy was performed, and he has worn the tube ever since. On one occasion the tube came out, and he was unable to replace it himself. He suffered from great dyspnœa, and "thought he should have died," but was brought to the hospital, where the tube was replaced. The object for which he now attended (May 17, 1882) was to get a fresh tube adapted. On oral examination a large perforation of the soft palate was at once seen, forming a free communication between the cavities of the mouth and nose. Behind this a large false membrane extended right across the fauces, completely barring the entrance to the pharynx. No opening whatever could be discovered for some time by probing in all directions with a soft œsophageal bougie, and it really seemed as if all the food must pass into the nose through the aperture in the soft palate and thence downward behind the false membrane into the œsophagus, but no bougie could be passed in this direction. On laryngoscopic examination, however, Dr. Prosser James discovered a small aperture at the base of the tongue, and demonstrated to the visitors present that a small-sized bougie could be passed through it and from thence into the stomach. On questioning the patient as to whether deglutition was not a very tedious process, he said he could not well manage to eat his dinner in less than fifteen minutes, and minced his meat—a very favorable state of things considering the narrowing that had taken place, and for the relief of which some operative procedure was plainly indicated. No trace whatever of the larynx was discernible, the view from above being entirely closed by the membrane above described. Freedom from respiratory trouble was only to be accounted for by the fact that the patient had always worn his tube.

By passing a larger bougie, Dr. James dilated the opening in the membrane somewhat, with the result that the following week (May 24th) the patient reported that he had been able to swallow better. Dr. James remarked that probably a considerable degree of dilatation could be effected by perseverance in this line of treatment, but that it was not likely to be permanent, that recontraction would probably occur on discontinuing the use of bougies. This method was therefore likely to be tedious and unsatisfactory, and it became a question whether more active operative measures might not only succeed in removing the obstruction but reveal the condition of the larynx and by bringing that organ within the range of treatment eventually enable the man to dispense with the tracheotomy tube. The galvano-cautery might be employed for the purpose, but he was rather inclined to a preliminary incision or splitting of the closing membrane by a specially shaped knife with a view of continuing operative procedures according to the condition revealed. He thought it quite possible to excise a sufficient amount of the abnormal growth to restore the normal functions of the parts, but would first place the patient on a course of specific treatment as a preparative.

CASE III.—James C——, aged forty-one, attended on May 31, 1882, for difficulty of breathing and speaking. On inspection it was seen that the whole of the soft palate and uvula had disappeared. He stated that his throat had been affected for nine years, and, on further questioning, a history of primary syphilis, twenty years ago, was elicited. Rhinoscopic examination was very easy, owing to the absence of the velum. The meatuses and the turbinated bones seemed healthy, but here and there particles of food were seen adhering to the membrane. The middle third of the septum on both sides was enormously swollen, giving the appearance at first sight of a pair of polypi. Laryngoscopic examination was rather difficult as the epiglottis was pendant, and the patient suffering from much dyspnœa Dr. James, however, demonstrated that both larynx and trachea were diseased. The vocal cords were both red and swollen—in fact, appeared as fleshy masses. The false cords were greatly thickened as also was the posterior wall of the larynx. The arytenoids were considerably enlarged. Below the vocal cords a thickish rough-looking proliferating mass was seen, somewhat resembling papillomatous growths and apparently arising from the anterior wall of the trachea. It was covered with offensive secretion, on the removal of which, by coughing, some ulceration was visible. The abnormal growth considerably diminished the calibre of the trachea, and to the stenosis thus produced was obviously due much of the dyspnœa. On auscultation, considerable emphysema of both lungs was found. Inspiration was specially difficult, each effort drawing in the thoracic walls and the larynx moving spasmodically. The dyspnœa had got rapidly worse during the last three months. Dr. James considered that the patient's future depended chiefly on the tracheal stenosis. It was, of course, impossible to see how far down this extended, the view of the lower part of the passage being occluded by the growth in the upper. This

might possibly lessen under treatment and further exploration by laryngeal probes become possible. If the trachea could be opened below the growth, he would recommend the operation being done, notwithstanding the emphysema—that is, if no reduction of the growth were brought about by treatment, and, in any case, he would deem it proper to risk the operation rather than let the patient die asphyxiated. Delay, however, was indicated by the ulceration, which process was likely to extend down the trachea and might be arrested by treatment. The patient was ordered to take an iodide of potassium mixture three times a day and three grains of gray powder thrice daily also.

Case IV.—Julia F——, aged forty-five, has been attending since August 17, 1881. She attended then for tertiary syphilis affecting the fauces. There was then ulceration of both anterior pillars, the entire uvula and velum, and the posterior pillars. There was a perforation of the palate which had lasted twenty years. The patient was ordered iodoform pills and iodoform insufflations. The next week this was changed for an iodide mixture to be taken every three hours, and a sulpho-carbolate gargle to be used frequently. By September 14th the ulceration had completely healed, and the mucous membrane presented a healthy appearance. The patient was then put upon mercurial treatment and advised not to leave off attending. More recently she stated that she had suffered from epileptiform fits, on which account bromide of potassium was ordered.

Progress of Medical Science.

Diagnosis of Pott's Disease before the Stage of Deformity.—In a paper read by title before the New York State Medical Society (reprint from *Boston Medical and Surgical Journal*, 1882), Dr. Gibney enumerates some pathognomonic points that should be considered in the early diagnosis of spinal caries. In his experience, tenderness on pressure with the hand, or with the hot sponge, are usually found absent in the early stages of the disease, and, indeed, pressure should relieve rather than cause pain. Nor can the presence of yielding or soft spots be relied upon in forming an opinion as to the nature of the lesion, because they may be found in ordinary rickets. The common test of *forcible pressure*, or a blow on the head or shoulders in the long axis of the body, he holds to be dangerous, especially where the dorsal or cervical regions are diseased. In the general examination of a suspected case, attention should first be devoted to the duration of the symptoms, then the conduct of the patient during waking hours, and especially to the use he makes of his spine. Inquiry will usually elicit that a slight strain or jar has been followed by a cry of pain, the sufferer seeking relief in some special position that he finds by experience is effectual. The disturbed sleep of spinal caries is characterized by restless moanings and faint cries on turning, while in hip-joint disease there are sharp cries without waking. In examining the patient he should be stripped, and after the spine has been tested as to its mobility, the functions of the hip-joints should be investigated, and the pelvis explored, as well as the ilio-costal spaces, both by palpation and percussion. When the disease is located in the cervical and cervico-dorsal regions, among the earliest symptoms are found slight torticollis or modified opisthotonus, while the step is apt to be short and cautious; there will also be a compensating backward curve in the dorso-lumbar region and the head sinks down between the shoulders. The irregularly acting diaphragm will also assist in locating the seat of the disease, as the fourth and fifth nerves are of necessity implicated. The pharynx should then be explored for tumors. When the first or second vertebra is the seat of the disease, occipital neuralgia will be present in almost every case.

When the disease is confined to the dorsal region, there will be an absence of the head symptoms, and the pain will be referred to parts on a level or below the vertebra affected. There will be a lordosis rather than a projection of the spine. When the lower dorsal region is affected, tumors may present in the ilio-costal space before any bony deformity manifests itself. When the lumbar region is the seat of the difficulty, the early symptoms will be confined to the limbs; there will be lameness or stiffness and the symptoms will last a long while; flexion of the thigh, which is at first slight, gradually becomes more pronounced. But attention should now be especially devoted to the hip-joint, which will be found normal in every respect. Presently a soft tumor appears in the groin or in Scarpa's space. Dr. Gibney holds that a *soft tumor* in this location, when preceded by a lameness that has persisted for some weeks, and in the absence of hip-joint disease, constitutional disturbance, injury, or intestinal difficulty, indicates disease of the last dorsal or first lumbar vertebra. Dr. G. also calls attention to a point brought out in a report to the Therapeutical Society by Dr. T. E. Satterthwaite (Medical Record, August 21, 1880), that Pott's disease is frequently associated with caries of other joints. He therefore urges that in all such suspected cases a thorough examination should be made of all the joints, lest an important complication be overlooked. Dr. Gibney bases his paper upon an examination of the records in one hundred and ninety-six examples of Pott's disease that came under his inspection during the year ending December 31, 1881.

Treatment of Contraction Following Hip-Joint Disease, by Means of the Weight and Pulley.—Extension has been used in many different ways to correct deformities, resulting from hip-disease, but never in exactly the manner practised by Dr. E. H. Bradford, who has described his experience in a paper before the Boston Society for Medical Improvement, January 9, 1882. In three cases, where the thigh was flexed at about a right angle with the axis of the sacrum, after the application of a ham-splint, traction was exerted by weight and pulley so that at the end of one week, in the first case reported, the leg was brought into a line with the axis of the body.

In the second, at the end of a fortnight, the extension was exerted in a line with the bed on which the patient lay, and some eight weeks later, with the ham-splint still in position, the patient was allowed to walk about the ward, and finally was discharged with his limbs nearly parallel. The third case was that of a child, three years old, delicate, but fairly nourished. At the end of three weeks the deformity was so far improved that no tilting of the pelvis occurred when the limb was placed on the bed. In this case advantage was taken of the direct weight of the leg, which is no small factor, as shown in a case of Dr. B.'s of nineteen years' standing, when

the deformity attained an angle of 70°, and the patient was compelled to wear a shoe raised five inches from the ground. In this case a ham-splint was so applied as to immobilize the knee-joint when the leg was extended. As soon as the patient became accustomed to the presence of the splint she was allowed to walk about at will.

In this way treatment could take effect only while the patient was standing. At the end of six months two inches was removed from the sole of the shoe, and the patient could rest the whole weight of her body upon the affected limb. In cases of short standing, when only a slight deformity exists, Dr. B. finds slight traction, without regard to the line of deformity, is effective in a very short time. The skin, in the groin, will at times be considerably stretched, causing nocturnal pain, but no serious complication has ever occurred under his supervision.—*Boston Medical and Surgical Journal*, January 19, 1882.

Failure and Success in the Treatment of Traumatic Tetanus.—Dr. Charles T. Beck, of New York, reports a fatal case of traumatic tetanus, in which the treatment by eserine was an important feature (*Medical News*, May 13, 1882). The patient, a well-developed boy of sixteen, was injured in the foot by a rusty nail. The wound attracted but slight attention for a week, but at the end of this period tetanic symptoms were established. Atropia and morphia were then administered hypodermically, one-thirtieth of a grain of the former with one-half grain of the latter, and were rapidly followed by chloral hydrate and bromide of potassa. After twenty grains of the former and half a drachm of the latter had been given, with inhalations of chloroform—all without success,—eserine was resorted to as suggested by Dr. Thomas Layton (*Medical News*, March 25th). At first one sixty fourth grain doses per hour were exhibited, the chloroform inhalations being continued, but without visible effect. The eserine was then advanced to one forty-eighth grain every hour, and the patient appeared to improve steadily under this dose until the following morning, when all the symptoms became more pronounced. Still hopeful of the eserine, it was pushed to one twenty-fourth grain every half hour, but there was no reduction in the force or frequency of the spasms, and the patient, continuing to fail, sank and died early in the morning of the tenth day. In the *Lancet* (April 8, 1882) Mr. Millar reports a successful case treated with syrup of chloral (B. P.). The patient, aged forty-three, was severely lacerated in his side and shoulder by the wheels of a threshing machine. The wounds were dressed with carbolic lotion (1 to 40), and the patient's progress toward convalescence was satisfactory until the eleventh day, when sore throat and difficult deglutition were noted. Three days later his neck was found red and tender to the touch. On the morning of the eighteenth day it became clear that tetanus had set in. A hypodermic of morphia (one sixteenth grain) relieved the severity but not the frequency of the contractions, but a drachm of the syrup of chloral administered *per orem* produced a decided amelioration in the severity of the attacks. The patient was then directed to take one drachm per hour while awake. After the third dose he slept for three hours and the paroxysms became less regular in their appearance and less severe. He was then ordered to take the chloral less frequently, but on the following morning being worse, the hourly doses were again prescribed; five days later he could sit up in bed. The dose of chloral was now increased to a drachm and a half, but to be taken only when specially indicated. The patient continued to improve until he was discharged cured, six weeks after the reception of the injury.

Omphalitis and its Complications.—Anna Lukens, M.D., Resident Physician to the Country Branch of the Nursery and Child's Hospital, Staten Island, treats of omphalitis of the new-born, in a paper published in the June number of the *New York Medical Journal and Obstetrical Review*. After giving an illustrative case, she remarks that the disease is of rare occurrence, but that it is said to occur even during fœtal life, by the movements of the child causing traction upon an unusually short cord, or one that is wound around the body of the fœtus. As described by Hennig, there are four varieties: 1. A mild form, in which the navel is prominent, the surrounding skin is reddened, the abdomen is distended, and, when the abdominal walls are thin, the vein can be felt as a cord extending from the liver to the umbilicus. 2. In the second or severe form, the navel is infiltrated and surrounded by a reddish-blue circle. Erysipelas frequently occurs, and extends over the abdomen and the lower extremities. There is greater distention of the abdomen, even when peritonitis does not occur, than in the mild form. The urine is sometimes bloody or icteric. The stools are greenish or bloody. Movements of the inflamed navel are painful, and may cause convulsions or trismus. Recovery is rare in the severe cases, but may occur after the disease has continued two or three weeks. 3. The third variety is the croupous or diphtheritic. The peritoneum behind it is usually involved in the inflammation, and frequently the contiguous coil of intestine. 4. The fourth variety consists of an inflammation of the tissues surrounding the umbilical vessels within the abdominal cavity, and often accompanies puerperal disease. It is usually limited to the vicinity of the navel, but may extend along the course of the umbilical vein to the capsule of Glisson. Early in the disease the umbilical vessels are not affected, but they subsequently participate in the inflammation, and necrosis may occur from compression by the shrinking exudation. The peritoneum is at first only locally injected; afterward a yellowish infiltration separates it from the posterior wall of the umbilical fossa. Omphalitis may occur primarily, or secondarily to other diseases. It is attributed sometimes to anomalies in the closure of the navel, to rough handling, to uncleanliness, to impure air, or to puerperal infection. Peritonitis and thrombosis of the umbilical vessels, with subsequent phlebitis and arteritis, are frequent complications. Umbilical hemorrhage, icterus, and pyæmia may also occur. Umbilical phlebitis may be produced by purulent matter entering the vessels from the fossa of the umbilicus, also by traction on the cord or tight bandages, or it may be secondary to omphalitis when non-involution of the umbilical vein exists. Thrombosis sometimes has an intra-uterine origin. Inflammation of the umbilicus, and especially of the outer walls of the umbilical vessels, is an important factor in causing non-involution. Besides other causes, thrombosis may also be due to defective nutrition of the vascular walls themselves, arising from a general septic poisoning, causing pyæmia or septicæmia. Whereas, on the one hand, thrombosis may occur from septic absorption, so, on the other,

there may be general septic poisoning after involution of the vessels, when no thrombosis can occur. The infection may be limited by thrombosis *in situ* of the umbilical vein, just as the uterine lymphatic glands may sometimes limit the diffusion of poison in puerperal infection. The principal danger in thrombosis of the umbilical vessels is the softening and breaking up of the coagulum, with the formation of distant emboli. As the umbilical vein is, of all the blood-vessels peculiar to fœtal life, the first to undergo involution, and is even at birth sometimes found considerably contracted, softened clots can rarely be admitted to the venous blood through the ductus venosus. Even an embolus in the liver is an exceptional occurrence. A coagulum at the entrance of the umbilical vein into the portal vein has been frequently observed, but is believed to be a local thrombosis and not an embolus. Thrombosis sometimes, though rarely, extends from the umbilical vein into branches of the portal vein. In regard to the pathological anatomy of umbilical phlebitis, the vein frequently presents a hard, cord-like feeling, the walls being thickened and often unevenly dilated. The contents may consist of simple disintegrated coagula or of uniform laudable pus. Sometimes the pus column is separated by cheesy masses. Occasionally a pseudo-membrane is found lining the vein. The intima and middle coat finally dissolve into a mass of white blood-corpuscles. The liver is sometimes, though rarely, affected. Bednar once found, in umbilical phlebitis, the hepatic vein inflamed, and nearly all its branches filled with pus, which, on section of the liver, flowed out in great quantities. Emboli in the hepatic branches of the portal vein have not been clearly demonstrated. When inflammation of the connective tissue around the umbilical vein extends to the capsule of Glisson, the latter becomes swollen and infiltrated. The inflammation may extend to the hepatic parenchyma, and by compression of the bile-ducts produce mechanical icterus, which assumes, however, the malignant form. The symptoms of phlebitis are a cyanotic or icteric hue of the surface. Pemphigus vessels and hemorrhagic abscesses are frequent. Gangrene, especially over the sacrum and of the navel, may occur. The purulent contents of the vein can sometimes be pressed out through the umbilical fossa. The umbilicus becomes prominent and indurated. The cord may have fallen or be still adherent. The inflamed vein can sometimes be felt through the abdominal wall. Next to peritonitis, meningitis is the most frequent complication. Peritonitis may be circumscribed or general. The peritoneal fold surrounding the umbilical vein is often the starting-point of the inflammation. Phlebitis is often only recognized after the appearance of purulent infection. It occurs between the first and twenty-eighth days, most frequently on the seventh. The fatal termination may be either from general septic poisoning, from peritonitis, from embolic infarction and metastatic abscesses, or from thrombosis in important vascular territories. Inflammation of the umbilical arteries may be confined to the seat of the coagulum, the remaining portion of the vessel being contracted or even closed. The coats of the vessels become swollen and gradually disintegrate, and finally perforation occurs. The adventitia is the seat of the principal changes, which readily extend to the surrounding tissue. Arteritis may occur after the umbilicus is almost or entirely healed, and the latter may afterward begin to protrude, inflame, and suppurate. Pus can sometimes be pressed out by making pressure upward from the bladder. At times there is retention of urine, with painful micturition, and sensitiveness in the region of the bladder. Icterus and peritonitis may occur, but belong more particularly to phlebitis. The contrast between arteritis and phlebitis is striking. Arteritis is rarely accompanied by fever, icterus, or pyæmia, and is almost always cured. Phlebitis has all the above-mentioned complications, and is almost always fatal. Arteritis is rarely a cause of general infection, but pyæmia may occur by purulent matter from the arteries being taken up from the umbilical fossa by the vein. This occurs more easily when the navel has been closed or healed over. Or infectious material could pass, in the opposite direction, into the pelvic blood-vessels, and from these into the general circulation. The neighboring lymph-vessels can also take up molecular detritis and carry it into the circulation. Thrombosis of the ductus Botalli has been observed in arteritis but oftener in phlebitis.

Intra-cranial Disease and Choked Disc.—Dr. Edward G. Loring contributes to the June number of the *New York Medical Journal and Obstetrical Review* an article on the nervous connection between intra-cranial disease and choked disc, the conclusions of which are: 1. That the vaso-motor theory, as advanced by Benedikt, is not sufficient to explain either the mode of transmission of the morbid irritation within the head, or the resulting neuritis optica. 2. That the irritation is conveyed, not by the isolated fibres of the sympathetic system, as stated by Benedikt, but through the agency of the trigeminus. 3. That choked disc or papillitis, in connection with brain disease, is the expression of an irritation or compression of certain intra-cranial fibres of the fifth pair, which preside over the blood-supply of the disc and neighboring parts, and also maintain the healthy processes of waste and repair of the tissues themselves. This being so, he adds, the same analogies and distinctions between "irritation" and "inflammation" can be made here as with sympathetic ophthalmia, so that here, as well as there, the irritation may exist as such for an indefinite time, or may so reduce the vitality and resisting power of the tissue of the disc and surrounding parts as to develop gradually, or explode suddenly, into an actual inflammation—that is, into a neuritis. The immediate and exciting cause of this neuritis may then be either an external one, such as exposure to cold or heat, over-exertion, either mental or physical, or, indeed, too much exposure to light, the effects of which, under the weakened condition of the organ, may be looked upon as a "traumatism"; or the exciting cause may be an internal one, such as some irritation from the condition of the blood and circulating fluids, either chemical or mechanical, either local or general, which, insufficient in itself to produce any bad effect upon a normal disc, may yet be just sufficient to produce a condition of inflammation in a part that is weakened and irritable.

A Very Rapid Heart.—Professor Pribram is reported in the *Wiener Mediz. Wochenschr.* as saying that he has had a case of "vagus neurosis" in which the pulse reached three hundred beats a minute! Professor Pribram must have employed Bunnell's lightning calculator in order to have counted it.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, July 22, 1882.

A STUDY OF WINTER HEALTH RESORTS.

In a study of the subject of winter health resorts, by Dr. Burney Yeo, recently published in the *Fortnightly Review*, some facts are collected which will be found valuable for the general practitioner.

Dr. Yeo first discusses the rationale of the so-called mountain cures. He considers it a mistake to suppose, as has been done, that elevation is the essential. It is shown that immunity from phthisis exists at very different levels in different parts of the world. Thus, in the Peruvian Andes, patients are sent to a height of 10,000 feet; in Mexico they ascend to valleys 6,500 to 7,000 feet above sea-level; in Colorado the elevation is between 5,000 and 6,000 feet. In the Pyrenees phthisis is rare at elevations varying between 2,000 and 4,500 feet. In some parts of Switzerland localities 3,000 feet high are as free from consumption as are others of twice that altitude. In the Black Forest and in Silesia an immunity exists at from 1,500 to 2,500 feet. We might cite our own Adirondacks as having, though at a low level, a good reputation as a health resort. The Russian physicians send their phthisical patients to the Steppes of Tartary, some of which are even below sea-level.

Elevation is, therefore, according to this author, only one of the factors in mountain cures. Purity of air is thought to be the chief curative agency, the air of mountain cures being generally quite free from all organic dust.

Stillness is another element. Most of the elevated health-stations are in valleys quite protected from the winds. This fact, in connection with the rarity of the air, has, however, an unfortunate tendency eventually to injure mountain health resorts. As soon as they get a reputation a population accumulates, houses are built, and the smoke being too heavy to ascend in the thin air, and there being little wind to blow it away, it hangs over the town in a cloud. This is the case at Davos, and, as we are informed, at places in Colorado. In addition, drainage is neglected, and the dangers of cesspools added.

There is one peculiarity of high altitudes, which no doubt is of therapeutic importance. This is the intense heat of the direct rays of the sun. At Davos, on January 31st, the mercurial thermometer, with blackened bulb, in the sun recorded 158° F. In the shade the record was only 41.5° F. At Greenwich, England, the thermometer in the sun on the same day reached only about 71.5° F. The curious fact exists that patients go out to walk in the snow, taking umbrellas to protect themselves from the sun. This intense heat of the sun's rays enables the invalid to remain out of doors on very cold days. The dryness of the air further helps to make the cold endurable.

The equability of temperature, especially as regards diurnal temperature, does not, of course, exist at high altitudes. Dr. Yeo is inclined to place less value upon this factor than is usually done. In the very equable climate of Ceylon consumption is quite prevalent. The fact is that changes of temperature have a very different therapeutic effect, according as they occur quietly and diurnally, or more slowly and with blustering storms and rain; also according to the especial local peculiarities of the climate.

The rarity of the air is the thing which, next to its purity, makes mountain resorts distinctive in their effects. This causes a rapid respiration, and forces into action every part of the lungs; and functioning tissue does not degenerate.

Dr. Yeo finally gives a summary of the classes of cases which are suitable to high mountain health resorts. This summary, which is quoted by him, is not a new one, but it condenses fairly medical experience up to the present time, and may be profitably inserted here:

First.—Where there is an obvious and well-ascertained predisposition to consumption, and when perhaps a slight hemorrhage has occurred without the manifestation of any definite local disease; as a *preventive* measure a residence for two or three seasons in a high mountain station is to be recommended.

Second.—In catarrhal forms of consumption, in the early stage, without much constitutional disturbance, the best results may be looked for. But cases with much fever from the commencement, and of nervous and excitable temperament, must not be sent to high altitudes.

Third.—Chronic inflammatory indurations and infiltration of limited portions of the lung, often the result of acute congestions and inflammations, are especially suitable; not so, however, if a considerable extent of lung is the seat of tuberculous disease, or if, owing to the extent of lung involved, and consequent changes in the sound lung, there is much difficulty of breathing.

Fourth.—Cases of chronic bronchial catarrh in

young people; that is to say, those cases of tendency to repeated attacks of "cold on the chest," often left behind in children after whooping-cough, measles, and other maladies.

But this does *not* apply to the chronic winter coughs of persons more or less advanced in life; or to cases where there is much *permanent* shortness of breath.

Fifth.—The results, in the shape of thickenings and adhesions, of former attacks of pleurisy, to which too often the development of serious subsequent lung disease can be traced. The pulmonary gymnastics excited by treatment in high altitudes prove of great value in these cases.

Sixth.—Many cases of purely nervous asthma have been cured in these resorts.

Seventh.—Apart from cases of pulmonary disease, many other ailments, such as general loss of power, not dependent upon organic disease—cases of nervous exhaustion, overwork, retarded convalescence, in otherwise vigorous constitutions, certain forms of dyspepsia and hypochondriasis, and other less strictly definable maladies—not seldom find restoration to health and strength from prolonged residence in the pure bracing air of these Alpine stations.

FURTHER CONTRIBUTIONS TO THE ETIOLOGY OF TUBERCULOSIS.

LANLANIE makes some observations (*Comptes Rendus*) regarding the origin of tuberculosis in a dog. He found in the lungs of this animal appearances closely resembling true miliary tuberculosis. The tubercles were due, however, to the presence of the eggs of a parasitic worm (*strongylus vasorum*). This parasite in its adult state, we are told, gets into the right ventricle and pulmonary artery, where it fastens itself to the walls. It here lays its eggs, which are carried by the blood-stream to the lungs, where they lodge and develop by irritation an apparent tuberculosis. The microscopical appearances of these tubercles closely resemble those from other causes, and confirm the view that the miliary tubercle has no anatomical specificity.

Dr. P. Ehrlich announces a new method of showing the bacillus of tuberculosis. It is a great improvement upon Koch's, because, as he tells us, one can see larger bacilli and more of them! The author rather thinks also that these bacilli have a capsule. Dr. Ehrlich is accustomed to use phthisical sputa in order to demonstrate the organisms. Portions of this are teased out, pressed between glasses and dried.

His staining fluids consist of a watery solution of pure aniline, to which is added a little saturated alcoholic solution of methyl violet until opalescence appears. The sections are allowed to stay in the staining fluid from fifteen to thirty minutes. They are then removed and blanched by a few seconds' immersion in nitric acid and water (1 to 2). This acid takes the color away from all but the bacilli. Dr. Ehrlich thinks that mineral acids harden the capsule of the bacillus and make it opaque. On the other hand, the alkalies soften it and allow staining fluids to enter. The inference is drawn that the disinfectant of the future for phthisis will probably have to be of an alkaline reaction.

We submit Dr. Ehrlich's account of his discoveries without comment, since it is too early to make positive statements regarding it. Doubtless our readers will follow his descriptions and reasonings with the intellectual interest, at least, that attaches to all things transcendental.

OUR HOSPITALS.

THE "Medical Register" for the present year gives a very complete and a very long list of the hospitals in this city and in the State. It is well known that New York has a great many charitable institutions. We doubt, however, if our citizens or even our medical men realize how large this number is, and in what disproportionate amount New York City expends money upon her sick.

There are nearly forty different public and private hospitals in the city, having a capacity of over 7,000 beds. Fourteen of these are entirely or in large part supported by the public, and they hold about 5,000 patients. Considerably more than one-half of the sick, therefore, are cared for at the city's expense.

The majority of the twenty-five private hospitals are for treating special classes of cases. This large number of special hospitals is now a feature peculiar to New York. There is no other city in the country which has so many. Not a few of them, also, are costly structures and finely equipped. The eye, ear, and throat hospitals are most numerously represented, though, in capacity for treatment, the hospitals for women and for children take the lead. Most of the large public hospitals have wards devoted to one or other special class of diseases.

It is when we compare the hospital accommodations of this city with those of the rest of the State, that one realizes their great extent. Brooklyn, with a population one-half as great as that of New York, has but eight hospitals, with a total capacity of about one thousand.

In the whole State, outside of New York and Brooklyn, there are, according to the "Register," but thirteen hospitals, having a capacity of less than two thousand.

New York has, therefore, not quite twice as many hospitals, but more than twice as many hospital-patients as all the rest of the State.

These facts will suggest to the physician the immense clinical opportunities of our city. But they will naturally awaken the tax-payer to thoughtfulness also. Our hospital population is made up, to no small extent, of the waifs of humanity attracted to the city, but unable to succeed in the fierce struggle for existence.

CREMATION.

The attention of the world has been drawn to cremation again by the news that Garibaldi wished his remains disposed of in this way. In a very timely manner it is announced that the United States Cremation Company has been licensed, under the general business act of 1875, to carry out the will of those desiring mortuary pyrotechnics.

The subject of cremation has now been before the modern public for a number of years. The novelty has worn away. People for the most part are no longer shocked at the idea, and they have lost some of the morbid interest in the details. Cremation can now stand upon its own merits. We believe that if careful provision against any medico-legal trouble be made there can be no objection to the process for those who have a taste for it. That it is necessary on sanitary grounds is not yet proven. Some cemeteries are unhealthy, but not all, and the real dangers from burial-places have no doubt been exaggerated.

On the whole, cremation, though it has appealed to the popular imagination, has not in the least obtained popular favor.

It cannot become a universally prevalent method of disposing of the dead. It will, perhaps, in time be adopted in closely populated districts when sanitary necessity supplements the other arguments in its favor.

THE BOYLSTON PRIZE AND MEDICAL WOMEN.

The Boylston prize has been awarded to an Englishman again, and our brethren of Boston are mourning the dulness and inactivity of the American physician. The prize was awarded to Mr. T. M. Dolan, F.R.C.S., of Halifax, England, for an essay on "Sewer Gas, its Physiological and Pathological Effects on Animals and Plants." This is the third time that the prize has gone out of this country, and the conclusion is becoming inevitable that there is no American, even in Boston, smart enough to get it.

We dislike to give advice, but perhaps in this emergency it will be pardoned. We would suggest to our Massachusetts friends that, since the men have failed so entirely, they give a little more encouragement to the women. It was a woman who gained one of the few European prizes ever taken by American physicians. When one is *in extremis* the help of the gentler sex is ever sought for, if it is only to lay out the corpse. Therefore we think of her now. But in the present trouble Massachusetts can expect nothing of her medical women so long as she maintains a, so to speak, sedentary posture upon them. The Massachusetts medical woman is in the anomalous position of having to join the homœopaths in order to get a standing.

We do not believe in special providences, but some who do, think that the annual departure of the Boylston prize from Boston to Europe is a visitation. And it is furthermore predicted that unless a less persimmon-like feeling soon prevails, the prize next time will be taken by some Russian female doctor who is not only an infidel, a nihilist, and an assassin, but who may even think Boston a small town in the West.

THE CONGRESS OF GERMAN SURGEONS.

It has been the custom for American surgeons to plume themselves upon being quite as good as any. There is good reason for this; at the same time, the papers and discussions at the Congress of German Surgeons, reported in another column, strikingly suggest that there is much to do yet before we attain pre-eminence. Certainly, our American Surgical Society is somewhat provincial when compared with the organization which met in Berlin last June.

Among the subjects most discussed at this Berlin meeting was, naturally, the treatment of wounds. The object of late experimentation seems to be to secure a dressing which is not only a perfect disinfectant, but which is also very absorbent. For this purpose, we find charcoal, sand, and "glass-wool," steeped in sublimate, paper ashes, dried peat, etc., recommended. One surgeon stated his belief that the iodoform era in surgery was over, and the impression is created generally that iodoform does not meet the demand for a model dressing.

The subject of the radical cure of hernia excited some discussion. Alcohol was recommended to be injected near the hernial sac, instead of the oak-bark solution used in America.

A highly interesting case was that of spleen extirpation, reported by Credé, Jr. The demonstration of the use of the œsophagoscope and gastroscope, by Mikulicz, the exhibition of excised stomachs, the reports upon the excision of the thyroid, the transplantation of muscle and the resection of the lung, naturally excited interesting discussions.

The characteristic of nearly all the papers read was that they represented something new in pathology or therapeutics, or operative procedure. A glance at the matter presented should have an educational value to the surgical societies, if not to the surgeons, of this country and England.

The Micro-Organisms in Acute Pneumonia.—Klebs, Ebert, Koch, and last Friedlaender (*Virchow's Archives*) have found micro-organisms in croupous pneumonia. They are of very similar size and form, being ellipsoidal in shape, nearly a micro-millimetre in length, and one-third less in breadth. Thousands can be seen within a single alveolus during the stage of red hepatization. In the majority of cases, they are not discovered in the alveolar or bronchial walls. Sometimes very large numbers are found in the lymph spaces.

Reviews and Notices of Books.

THE ANATOMIST: BEING A COMPLETE DESCRIPTION OF THE ANATOMY OF THE HUMAN BODY. Second Edition. With 171 wood engravings. By M. W. HILLES, formerly Lecturer on Anatomy and Physiology at the Westminster Hospital School of Medicine, etc. New York: G. P. Putnam's Sons. 1881.

ALTHOUGH originally designed as a condensed summary of the anatomical knowledge essential to the student about to present himself for examination at the Royal Colleges of Surgeons, this little work may serve as a cram-book for all English-reading students. It presents no special advantages over works of a similar character, except inasmuch as this second edition contains numerous small wood-cuts. Many of these are unusually good, being in part drawings from "Grey's Anatomy," considerably reduced in size, but still sufficiently large to aid the sorely-taxed memory of the student preparing for his degree.

A TREATISE ON THE DISEASES OF INFANCY AND CHILDHOOD. By J. LEWIS SMITH, M.D., Clinical Professor of Diseases of Children, Bellevue Hospital Medical College, etc. Fifth edition. With illustrations. 8vo, pp. 836. Philadephia: H. C. Lea's Son & Co. 1881.

As compared with former issues of this work, the present fifth edition shows an improvement in several respects. To begin with, the author has succeeded in enhancing the practical utility of the book by a greater attention to details of treatment. Then he has omitted, as far as practicable, the rather barren discussion of theoretical problems, which, as a rule, only disappoint the student or practitioner who consults works of this kind with a view to instruction, information, or corroboration. Finally, several new diseases have been added to the list of those described in former issues. Dr. Pomeroy has also furnished a satisfactory chapter on strumous ophthalmia.

The verdict of the profession on Dr. Smith's treatise may be read in the fact that this fifth edition has evidently been called for, and in its present shape the volume will give welcome assistance, both to the young physician who is starting on his career, and the established practitioner who needs occasional consultation of a largely reliable text-book.

TEXT-BOOK OF MODERN MIDWIFERY. By RODNEY GLISAN, M.D., Emeritus Professor of Obstetrics and Diseases of Women and Children in the Medical Department of the Willamette University, etc. With 139 illustrations. 8vo, pp. 639. Philadelphia: Presley Blakiston. 1881.

AN obstetric voice out of the far West claims recognition, as "properly representing the peculiarities of American practice." Certainly a design of no mean ambition in an essentially *homo novus* in medical literature. For Emeritus Professor Glisan, of Willamette University, although an occasional contributor to the *American Journal of the Medical Sciences*, has yet to achieve a national reputation.

Meanwhile, the book before us is a good beginning, although it would be a rather poor ending. We apprehend that Glisan's treatise will not be able to largely replace the works of Leichman and Playfair, even in our own country.

Dr. R. P. Harris, of Philadelphia, has undertaken the supervision of the work, during its author's absence in Europe. And Dr. Harris appears to have become aware of the somewhat inadequate extent of Glisan's obstetric erudition, for he modestly emphasizes that the Western gentleman is an Eastern graduate, whose long experience has enabled him to obtain "that practical knowledge which gives a character and value to many portions of his work." This sounds like a confession or intimation that there may be some portions of the work which are deficient in such character and value. If Dr. Harris intended to be so understood, it argues well for his powers of discernment, because there are indeed "portions of the work" that must needs be rewritten before the book can presume to fairly represent American obstetric practice.

Doubtless the author has brought much diligence to bear upon the preparation of the volume before us, and that he has had an extensive obstetric experience no one will attempt to deny. But these are not the only qualifications which the author of a distinctly representative manual must possess before he can hope to receive universal recognition. The style of the book is often decidedly too chatty, wanting in true dignity, or mixed with the verdant flavor of the prairies.

Themes, illustrations, comparisons, and typical cases are drawn from a grab-bag, as it were, of a richly-varied experience, sometimes too richly varied. Yet the book is not without its substantial value, and especially the Western practitioner about to launch forth on his obstetric career can profitably read many a chapter of Glisan's treatise. With some judicious pruning, remodelling, with a little excision here and transplantation there, the book, even without a major operation, may change its countenance to such an extent as to make the second edition a true and fair exponent of American obstetric practice, which this first issue is only in part.

A HANDBOOK OF UTERINE THERAPEUTICS AND OF DISEASES OF WOMEN. By EDWARD J. TILT, M.D., Past President of the Obstetrical Society of London, etc. Fourth edition. New York: W. Wood & Co. 1881.

THE fourth edition of Dr. Tilt's practical treatise, although written several years ago, will still be found a useful and suggestive work to peruse. In spite of the fact that some very modern methods of treatment are necessarily conspicuous by their absence from the pages of this book, the author has so judiciously presented his subjects that little fault can be found with the manual. In fact, if a later revision had removed from it the traces that time has left, we could desire no more practical and common-sense treatise on uterine therapeutics than the present one. The body of the book will, nevertheless, be found to contain many lessons which may be as profitably learned to-day as they were a few years ago.

ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE: A Handbook for Students and Practitioners. By HENRY HARTSHORNE, A.M., M.D., lately Professor of Hygiene in the University of Pennsylvania, etc. Fifth edition. Philadelphia: H. C. Lea's Son & Co. 1881.

THE present fifth edition of Hartshorne's treatise is essentially a somewhat modernized fourth edition. What was said of the former issues applies equally to this one. The author in endeavoring to do justice to the progress of medcine, has condensed within a very small compass much that is needful and essen-

tial to an understanding of the practice of medicine. But certainly many important details and notably valuable points in differential diagnosis must necessarily be omitted in a work of this kind. For the beginner, the book will serve its purpose, by familiarizing him with the elements of practical medicine, but the advanced student, and above all, the practitioner, will consult the book in vain for points not sufficiently explained in the lecture-room. Thus, while the book is valuable in its own limited way, it cannot in any sense replace the larger manuals on the subjects of which it treats.

A MANUAL OF OPHTHALMIC PRACTICE. By HENRY S. SCHELL, M.D. With 53 illustrations. 8vo, pp. 263. Philadelphia: D. G. Brinton. 1881.

THE author states that his object in writing this book is to give briefly the generally accepted principles of ophthalmology and to describe those methods of treatment upon which he has become accustomed to rely.

We can find no fault with the way in which Dr. Schell has carried out his purpose. The book is well written and has a sufficient number of good illustrations.

The recommendations for treatment are judicious. Regarding mooted questions, the author rather quotes authorities than insists upon his own. We should consider the book a very useful one to students and the general practitioner.

LECTURES ON THE PATHOLOGICAL ANATOMY OF THE NERVOUS SYSTEM, DISEASES OF THE SPINAL CORD. By J. M. CHARCOT. Translated from the Reports by Dr. E. Brissaud in the *Progrès Medicale*, by CORNELIUS G. COMEGYS, M.D. With illustrations. Cincinnati: Peter G. Thomson. 1881.

THE lectures contained in this book number seventeen. They cover the subject of the physiology and of the normal and pathological anatomy of the spinal cord. The secondary degenerations of the different tracts of the cord are especially dwelt upon. Prof. Charcot attempts here to furnish not a complete history of diseases of the cord, but rather the pathological anatomy of systematic and focal lesions with their relation to symptoms. This branch of the subject as well as much of value regarding the physiology of the cord is given most lucidly. Indeed to the American reader, the efforts of the lecturer to be clear are a little burdensome.

The translation is not a model for such kind of work, but no serious errors are made. The illustrations are poor, yet answer their purpose fairly well. The book is, of course, authoritative in the branches of which it treats.

THE ART OF VOICE PRODUCTION, with Special Reference to the Methods of Correct Breathing. By A. A. PATTOU, Author of "The Voice as an Instrument." New York: G. P. Putnam's Sons. 1882.

WHEN attention is called to the announcement in its official circular, that the American Laryngological Association has selected for one of the discussions at its meeting this year the subject "The Singing Voice, its Physiology, Pathology, and Treatment," no apology need be offered for the appearance here of this notice. As a clearly written, scientific, and practical exposition of the true principles of voice production, the above work is the best upon the subject we have ever read. While writing from the standpoint of a thorough musician, the author has made, as evidenced by his constant reference to standard medical writers, an exhaustive study of the physiological aspects of his subject, so that his opinions carry double weight. His plea for, and his explanation of the true "abdominal method" of breathing, and his suggestions as to the value of systematic vocal exercises for the relief of various disorders of the larynx are eminently sound and useful, and will be found exceedingly interesting by all classes of readers.

AN INDEX OF COMPARATIVE THERAPEUTICS, with Tables of Differential Diagnosis, a Pronouncing Dose-list in the Genitive Case, a List of Medicines used in Homœopathic Practice, with Memoranda concerning Clinical Thermometry, etc. By SAMUEL O. POTTER, A.M., M.D. Second edition. Chicago: Gross & Delbridge. 1882.

WE reviewed this book a short time ago. But little change is made in the present edition. It is a work of considerable interest, but will be more useful to the homœopath than to regular physicians. It illustrates a conformity of practice between the two schools which is not generally suspected.

THE MEDICAL ADVISER IN LIFE ASSURANCE. By EDWARD HENRY SIEVEKING, M.D. Second edition. Philadelphia: P. Blakiston & Co. 1882.

THE second edition of this work is not materially enlarged, but contains an index and is in other respects improved. Dr. Sieveking has collected a good deal of information not found in ordinary medical works, and he presents it in a pleasing manner. His book is intended especially for medical examiners and those interested in life assurance. To these it will prove a very useful manual.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 26, 1882.

DR. EDWARD C. SEGUIN, PRESIDENT, IN THE CHAIR.

DR. CARPENTER presented a specimen of

ANEURISM OF THE THORACIC AORTA

in behalf of a candidate.

DR. JANEWAY presented specimens illustrating

FIBRINOUS BRONCHITIS—THROMBOSIS OF THE PULMONARY ARTERY—ABSCESS OF THE LUNG WITH GANGRENE—EMPYEMA.

They were removed from the body of a man fifty-two years of age, an Italian laborer, who was admitted to Bellevue Hospital. The following notes were furnished by Dr. J. S. Thatcher:

April 20th.—His friends stated that for many weeks the patient had complained of not feeling well, and for a month he had not been able to work. Nothing more definite could be ascertained. On the day of his admission he fell while walking on the street, and was brought in by an ambulance. On admission his face was darkly congested, and the pupils were contracted. The tongue was coated, brown in the centre, and very tremulous. He was stupid. There was no eruption (typhus was suspected). On physical examination of the chest, evidence was obtained of incomplete consolidation of the lower lobe of the right lung and bronchitis in the left. Moist râles were heard all over the chest. There was no expectoration. The area of

splenic dulness was perhaps a little enlarged. The urine was amber-colored, cloudy, acid, had a specific gravity of 1022, and contained ten per cent. of albumen. His temperature at 9 P.M. was 102½° F.

April 21st. — Temperature, 3 A.M., 101½° F.; 4 P.M., 103° F. This afternoon he laid in a state of coma vigil. Later he passed into coma, and his appearance was as if moribund, although his pulse was quite full.

April 22d.—Temperature in the morning, 102½° F.; in the afternoon, 103° F. His mind was clear. Pupils less contracted.

April 23d.—Temperature in the morning, 100½° F.; at noon, 99½° F., and in the evening, 98½° F. His mental condition and the appearance of his face were improved. He had yellowish watery stools twice a day.

April 24th.—Temperature in the morning, 98½° F.; at noon, 99° F., and in the afternoon, 100½° F.; pulse, 125, and feeble; respiration, 38. He had passed into a state of muttering delirium.

April 25th.—Temperature in the morning, 101° F., and in the afternoon, 100½° F. The diarrhœa continued, omitting one day. The other symptoms remained without special change, and in the evening he died.

At the autopsy there were found bronchitis in the left lung throughout, circumscribed adhesions over the lower lobe of the right lung, forming cavities which contained purulent fluid. On section of the right lung there were found (1) fibrinous plugs in many of the bronchi, (2) thrombosis of the pulmonary artery, (3) abscesses, two or three, with surrounding gangrenous condition of the lung tissue. Probably the abscesses gave rise to the empyema, as they were covered by only a delicate layer of pleural membrane.

The probabilities were that the bronchitis was the primary pulmonary disease.

The liver and spleen showed evidence of malarial fever, as indicated by their pigmented condition. Both organs were slightly enlarged. The other organs were normal.

The empyema was evidently secondary to the abscesses and gangrene of the lung, and due to transudation of irritative material through the thin pleura which covered them. There was no evidence of pyæmia in any other part of the body.

It was the second case of thrombosis of the pulmonary artery he had seen within a few weeks. In the other case he predicted its existence as a cause of death in a case of myelitis, and was led to the conclusion by the fact that there was thrombosis of the femoral, and the patient was in the condition of collapse.

The localized empyema, probably, would not have been reached by the introduction of a hypodermic needle, as could be readily seen by the specimen. The inability to obtain fluid by means of a needle introduced into the chest does not necessarily prove that fluid is not present.

In this connection Dr. Janeway alluded to

ANTE-MORTEM THROMBUS IN THE RIGHT VENTRICLE.

He had long believed that in certain cases where the right ventricle becomes overdistended and death occurs, if the right ventricle could be relieved of a small quantity of blood, life might be saved. Not long since he introduced the needle of a large hypodermic syringe into the right ventricle of the heart of a man, who had just died of tubercular meningitis, and drew off a syringeful of blood. The result was entirely negative. The blood removed was black and fluid. He then threw in a solution of carbonate of ammonia without effect. But the experiment helped to explain the significance of heart-clot; for at the autopsy the right ventricle was filled with a firm, whitish, fibrinous clot. It served to confirm the opinion he had long entertained, that the more or less firm coagula found in the right ventricle at autopsy, are of post-mortem origin.

Dr. Ripley referred to the fact that in a large number of cases where the chest was full of fluid, puncture had been made without obtaining anything, except it might be a slight quantity of blood. Sometime ago he met with a case in St. Francis Hospital that gave the physical signs of fluid in the pleural cavity, and he introduced the hypodermic needle twelve or fifteen times before obtaining any at all, and when obtained it was purulent. He then made a free incision and removed sixty ounces of pus. He thought it probable that the needle, when fluid was not obtained, entered the curds, of which there was an abundance in the fluid removed.

Dr. Janeway said he had made eight punctures with a needle before finding fluid in the pleural cavity. The more common explanations of failures were the existence of adhesions into which the needle entered, the presence of cheesy material, which clogged the needle, and imperfectly constructed instruments.

Dr. J. A. Wyeth presented specimens which showed results obtained by the use of

BROAD ANIMAL LIGATURES APPLIED TO ARTERIES.

They consisted of the carotid arteries of a woman, a greyhound, and a horse which had been deligated with carbolized nerves taken from a calf. Specimens of ox-aorta ligature prepared and sent to him by Mr. Barwell, of London, and others prepared by himself, which he had successfully used in tying the subclavian and the carotid arteries, were also exhibited to the Society.

The carotid had been tied in September, 1881, to relieve intense pain and to arrest the progress of a malignant growth which had destroyed the right eye, filled the cavity of the orbit, sinus maxillare, sphenomaxillary fossa, and the sinuses of the ethmoid, sphenoid, and frontal bones. The ligature was the full size of the sciatic nerve of a calf six weeks old, taken and immersed entire in 5 per cent. carbolic acid twenty-four hours before the operation. The wound healed by first intention. The patient died seven months after the operation from the spread of the disease, which was temporarily arrested by the operation. The artery was completely occluded and its continuity unbroken. A depression, almost imperceptible, extending for the fourth of an inch, marked the exact location of the ligature, every other trace of which had disappeared. The same result was achieved in the carotid subclavian of another patient upon which he had tied these vessels with broad ox-aorta ligatures for aneurism of the aorta, the patient having lived a year and died of an intercurrent affection, not connected with the operation or the aneurism.

The carotid of the dog was also tied with the nerve-ligature. Five weeks later the animal was killed, the artery was completely occluded and the nerve had entirely disappeared.

The carotid of the horse was not occluded. There was a slight elevation of the endothelia at the point of application, but the ligature had evidently slipped within a few hours of the operation. The horse was not anæsthetized and was plunging, so that it

was with great difficulty the ligature was applied. Dr. Wyeth believed that he did not do this operation well. The nerve-ligature had been entirely absorbed.

He cited about twenty cases in which the broad tape-like ligatures had been used, and secondary hemorrhage had not occurred in a single instance. The iliacs, femorals, carotids, and subclavians were the vessels tied. There could be no doubt of the safety and efficacy of these ligatures as demonstrated at first by Mr. Barwell. He believed the nerve-tissue was the best broad animal ligature; it was strong, easily prepared, easy of application, was soft by virtue of the white substance of Schwann within its neurilemma, and it pressed upon such a large area of the vessel that while it occluded it perfectly, bruising the intima so that proliferation of the endothelia resulted, it did not cut any coat of the artery, and therefore did not entail the risk of secondary hemorrhage. Catgut nor any other ligature was free from this danger.

Dr. Geo. L. Peabody presented specimens illustrating

BICUSPID AORTIC VALVE WITH RECENT ENDOCARDITIS, TOGETHER WITH A PECULIAR FORM OF DOUBLE CARDIAC ANEURISM, AND CEREBRAL HEMORRHAGE IN A BOY EIGHTEEN YEARS OF AGE,

This been removed from the body of an American boy, eighteen years of age, who recently died in a hospital in this city, having lived only five hours after his admission. During these five hours he was pulseless at the wrist and unconscious. His pupils were contracted. There were no other symptoms of interest; and he being obviously moribund, but little was done for him.

His mother said that he fell suddenly from his wagon while at work as a porter, and was picked up in an unconscious state. From his mother there were ascertained, also, these facts: Three years ago he had rheumatism, which laid him up for six weeks. Eighteen months ago he began to be troubled by swelling of the feet, which had been intermittent ever since then. During this same period he had complained of pain in his chest, which had never been severe. In addition to these symptoms he had been much annoyed by drowsiness during the daytime. It was an interesting fact that he had never complained either of dyspnœa or of palpitation.

The autopsy was made twelve hours after death. All the organs were substantially normal except the brain, heart, and spleen. The spleen was large, but structurally normal.

The brain presented an extensive hemorrhage in the left hemisphere. Just behind the optic thalamus, in the floor of the left ventricle, freshly coagulated blood made its appearance in the cavity of the ventricle, and upon cutting into the floor, the large blot seen was exposed. It extended nearly to the surface of the brain in a downward and outward direction, coming within a centimetre of the surface in the upper part of the sphenoid lobe.

The vessels at the base were normal and no embolus had been discovered. The brain in the neighborhood presented the usual small punctate hemorrhage which are found in the vicinity of a large clot. Search had not been made for miliary aneurisms.

The heart, so far as Dr. Peabody knew, was an unique specimen. There was a small amount of hypertrophy and dilatation of the left ventricle, and on one side the endocardium was distinctly thickened. There were but two cusps to the aortic valve, which were of the same size, signifying that the lesion was congenital. He had recently presented to the Society a heart which showed the same lesion. The two cusps were very deeply ulcerated, and upon them were situated large masses of fibrine. Just beneath the attached border of one of the cusps, and just above the attachment of the mitral valve, were to be seen two nearly circular openings in the endocardium and muscular walls, the diameter of one of which was about five millimetres, the diameter of the other being less than half of this size. These two openings lead into two small sacs on the outside of the heart, situated just above the auricular appendage on the left side. The larger of these sacs—which was in relation with the larger opening—was about large enough to contain a small-sized English walnut. At the autopsy it was found full of recently coagulated blood. The smaller of the two sacs was situated wholly within the larger one and was less than one-quarter of the size of the latter. It was interesting that these two sacs, whose walls were made of dense, firm, connective tissue, did not communicate with each other at all. There was, then, a double aneurism of the heart, of most peculiar character. Its situation, too, was extremely unusual for aneurisms of the heart.

It was to be regretted that the clinical history was so meagre.

(To be continued.)

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 9, 1882.

Dr. T. M. Markoe, President, in the Chair.

Dr. L. M. Yale read a paper entitled

CASES TREATED WITH PHENIC ACID (DÉCLAT).

Dr. R. F. Weir referred to the case mentioned by Dr. Yale in his paper, and also to a case of puerperal septicæmia, in Dr. Polk's service at Bellevue Hospital, that seemed to be benefited by the phenic acid treatment. His experience, however, in the use of the remedy in the New York Hospital had not been satisfactory. Recently the antipyretic influence of phenic acid had been tested in private practice in a case as follows: A man pricked his thumb with a thorn. An abscess in the hand followed, which was opened, and the swelling disappeared from the hand, but soon afterward the patient was seized with a chill. His temperature rose to 105° F., accompanied with great prostration, sweats, etc., and evidence of pleuro-pneumonia developed. He was put upon the use of phenic acid for three days, during which time the exacerbations remained unchanged, the temperature varying from 99° to 105°. He took in the time the equivalent of sixteen grains daily of pure carbolic acid, by injection, besides the ammonio-phenate syrup internally every two hours. The temperature was not at all affected by such dosing.

Such cases as these, as well as others, where the acid had been even more freely used, and in some cases of high temperature of surgical origin, where Lister's dressing had been followed by symptoms of marked poisoning, without a reduction in the temperature, would lead him to qualify materially the favorable impression he had at first received concerning the efficacy of phenic acid from its use in his wards at Bellevue Hospital during the early months of the year.

Dr. Stimson remarked that in the case of carbolic acid poisoning he had already reported, the temperature fell to 92° F., and remained subnormal four or five days. The case terminated fatally, but there were no signs of septicæmia after the first appearance of the symptoms of poisoning by carbolic acid, and he had regarded the case as one of cure of septicæmia, but death from poisoning by carbolic acid.

Dr. E. L. Keyes referred to cases in his service at Bellevue, which were entrusted to the care of Dr. S. Alexander, who was much interested in the method, and had carried it out thoroughly, in some cases in the service of Dr. Polk. One was a case of erysipelas of the foot, that seemed to do remarkably well, for it lasted only two days. Another was a case of erysipelas of the entire leg, and injections were used persistently, but no appreciable effect was produced upon the temperature, and the disease lasted ten or twelve days. He had seen it used in several cases where high temperature was present, but without the least effect.

Dr. Alexander got a dissecting wound, which was soon attended by considerable pain, swelling of the neighboring glands, etc., and he injected himself sub-cutaneously at appropriate intervals during twenty-four hours, with the effect, as he thought, of aborting the poisonous process.

Dr. Keyes had used the syrup of the ammonio-phenate in private practice, and the only case in which it seemed to exert a favorable influence was the following: A frail, anæmic young woman, two years ago, had considerable faucial erythema, and twenty-four hours afterward, facial erysipelas developed, beginning upon the nose. She was kept in bed ten days and then recovered. Last year she escaped. But in 1882 she came to his office on a certain day complaining of sore throat. On examination there was found upon the side of the soft palate, a patch of erythema an inch long, half an inch wide, and elevated an eighth of an inch. It was shining, had a distinct margin, and was livid red. The tonsil was not involved. The condition was similar to that which existed at first, two years ago. There was a febrile movement, and the patient had no appetite. The syrup of the ammonio-phenate was given, the patient recovered within two days and had no facial erysipelas. About a week afterward a patch of distinct erysipelas appeared upon the side of the nose, and while still taking the syrup in reduced doses. She then went to bed, took nothing except the ammonio-phenate, with milk and a small quantity of the tincture of iron. The erysipelas spread and covered the face, forehead, and both ears, but ran its whole course in about five days. He thought that in this instance the remedy shortened the duration of the disease.

Dr. C. K. Briddon referred to a case of suppurating fungous arthritis, which came under his observation in the Presbyterian Hospital. The temperature was from 102° F. to 104° F. Amputation was performed, and the temperature still continued high for two weeks, when the syrup of the ammonio-phenate was administered, and the temperature came down at once and remained, and the general condition of the patient had very much improved, appetite returned, etc.

Without making any definite statement, he had been aware of injections of the remedy being used on the medical side in the same hospital, but without any effect upon the temperature of the patients.

Dr. J. W. Howe thought it hardly fair to attribute recovery, in one of Dr. Yale's cases, to the phenic acid, while the patient was taking at the same time iron, whiskey, and digitalis.

Dr. Yale remarked that the improvement began after the use of phenic acid was commenced. However, he gave the cases for what they were worth, without special endorsement of the method, hoping to have its value somewhat disclosed by the discussion.

Dr. Weir also referred to a case of *tumor* in which the remedy had been used. Late in the Autumn of 1881, a patient came to him with a swelling in the submaxillary region, upon the left side, which followed a slight injury of the parts. It was hard and knobbed, and projected somewhat into the floor of the mouth, and led to the suspicion that it was sarcomatous in character. The patient was put upon large doses of arsenic, which was continued for some time, but apparently without effect, and was then discontinued. On seeing the patient a short time afterward, to discuss the advisability of an operation, it was found that the tumor had diminished somewhat in size. The patient remained only a short time longer under observation, but when last seen the shrinkage in size was marked. Dr. Weir learned that subsequently he had been treated by Dr. Déclat by spraying the external surface of the tumor and the inside of the mouth with carbolic acid, and by the internal use of the syrup of the ammonio-phenate. At the end of a month or six weeks the tumor disappeared. Dr. Weir was not aware that the tumor had been treated by injections of phenic acid.

His own experience in the use of carbolic acid (Calvert's No. 1 and Bowdler & Brekersdike's) did not encourage him to hope for much good from such injected into the substance of a tumor except in angiomata.

Dr. H. B. Sands said that he had been reluctant to accept the statements made in favor of the remedy, mainly because it had been announced as a kind of panacea. It seemed to him that if it possessed the marvellous properties ascribed to it, this fact would long ago have been corroborated in Dr. Déclat's native country. Dr. Sands did not wish to deny the value of carbolic acid in the treatment of erysipelas, but thought the evidence offered by Dr. Yale inconclusive. Erysipelas, like acute rheumatism, was a disease very uncertain in its progress, and one, therefore, in which it was difficult to estimate the effect of remedies. In the Roosevelt Hospital, last winter, he removed a parotid tumor. A few days afterward, erysipelas developed, and ran its course in three days. Recently a gentleman came to his office, with erysipelas of the scalp, and said that he had derived great relief from the application of Witch Hazel. He was allowed to continue the use of it. Several days afterward he presented himself again, having entirely recovered.

The case of pyæmia, related by Dr. Yale, was the most striking of all, and yet in that instance the disease was chronic rather than acute, which would throw it out as an illustration that the remedy has any efficacy in controlling the disease.

He had recommended a trial of the remedy in cases of malignant tumor which were inappropriate for operation, but had nothing favorable to report.

He knew of a case of enchondroma of the thigh occurring in a man forty-five years of age. The tumor had been growing for fifteen years, extended from the region of the knee to the hip, and its estimated weight was twenty-five pounds. Amputation was advised.

In the meantime injections of phenic acid were proposed, and accepted by the patient, and soon after one of these was given the patient was seized with a chill and subsequently died of pneumonia.

DR. KEYES had seen recovery take place in one case of diphtheria while the phenic acid was being used, and two patients, one sick with scarlet fever and the other with puerperal fever, had died while it was being employed.

HERNIA—REDUCTION BY TAXIS UNDER ETHER—SUDDEN DEATH AN HOUR AND A HALF AFTER COMING FROM UNDER THE INFLUENCE OF THE ANÆSTHETIC.

DR. YALE narrated a case as follows: A man, fifty-five years of age, had had a large hernia for many years, and had been in the hospital several times for its reduction. Once it was reduced after prolonged taxis, without an anæsthetic. Later it was reduced under an anæsthetic. The last time he entered the hospital the hernia had come down and formed a tumor that reached to within three inches of the knee. When Dr. Yale first saw him taxis had been resorted to and the tumor partially replaced, but there remained a mass as large as a good-sized musk-melon. He directed that a large enema be administered, taxis again be employed, and an anæsthetic be used if necessary. The other means failing, ether was given, and the hernia was reduced without special difficulty. The patient came from under the influence of the anæsthetic apparently, but about an hour and a half afterward was seized with coughing, as if something had entered the larynx. He became cyanotic, and the House Surgeon fearing that death was imminent, made an incision through the skin for tracheotomy, when the patient coughed out what seemed to be strangling him, and at once breathed freely, but without a renewal of the difficulty of breathing he suddenly expired.

The autopsy was conducted by Dr. Janeway, and nothing was found to account for the sudden death.

Dr. Yale regarded it as belonging to the class in which death occurs late after the use of an anæsthetic.

DR. WEIR referred to the explanation given by Hunter, of Philadelphia, of some of the deaths which occurred late after the use of anæsthetics—namely, from Bright's disease, the existence of which had been unknown until revealed by autopsy.

While an interne in the New York Hospital, a man came in with a large hernia, which was reduced, and the patient suddenly died, and the explanation then offered was that death was caused by the sudden return of a large mass of intestines to the abdominal cavity.

THE PRESIDENT said that it would almost seem as though there was some direct relation between the reduction of large herniæ, the administration of an anæsthetic, and sudden death. Several years ago he had a case, in which the patient died while upon the table.

REMOVAL OF A PORTION OF A NEEDLE FROM THE ARM.

DR. A. C. POST referred to the case of a man who appeared at his clinic complaining of some foreign body under the skin of the arm. An incision was made and the body found to be the pointed end of a needle a little more than two centimetres in length. It was there without any knowledge on the part of the patient as to how it came there.

CONTRACTED PREPUCE.

DR. POST also referred to the case of a child, a little more than a year old, that had a long prepuce, but not contracted so that it could not be drawn back. With some difficulty he succeeded in clearing it from the glans as far back as the corona. But he performed circumcision, and released the parts entirely. He supposed that the agglutination or adhesion was due to a low grade of inflammatory action excited by lack of cleanliness.

DR. WEIR suggested that the adhesion might be due to lack of development.

DR. POST remarked that he was able to separate the prepuce from the glans without the flow of blood, although it was exceedingly close.

POST-PHARYNGEAL ABSCESS.

DR. H. B. SANDS narrated a case as follows: About two months ago he was called to see a patient, in consultation with Dr. J. Lewis Smith, and was asked to open what was thought to be a glandular abscess in the neck of an infant. The patient was a puny child, about six months old, who had been sick for two weeks with symptoms of inflammation of the neck: Upon examination, a tumor, previously noticed, was seen lying in front of the sterno-mastoid muscle, extending up to the angle of the jaw, and reaching downward half way to the clavicle. It was not very prominent, was soft, apparently fluctuating, and quite yielding. On inquiry it was found that the child had some difficulty in swallowing and breathing, and, at the time, respiration was embarrassed and the child breathed with a loud noise. Dr. Sands suspected the case to be one of post pharyngeal abscess, and Dr. Smith had entertained the same suspicion, but the result of his examination had been negative. Dr. Sands introduced his finger into the throat, but was not satisfied that there was any swelling in the pharynx. At the same time he was not certain as to the existence of abscess of the neck, and therefore proposed to tap the swelling, and if pus was obtained to evacuate the abscess by incision. No ether was given. He thrust the hypodermic needle into the swelling to the distance of an inch, but obtained no matter. A second puncture was made, with a negative result. He then examined the tumor a little more carefully by palpation than he had done before, and was surprised to find that it almost entirely disappeared, the neck becoming nearly as flat as upon the opposite side. He then again explored the throat with the finger, and detected a bag-shaped swelling just where post-pharyngeal abscesses are usually found. He then proceeded to use a tongue depressor, and the moment the part was exposed to view the child ceased breathing, became cyanotic, and seemed likely to die. Without seeing the parts, but using the forefinger as a guide, Dr. Sands thrust a knife into the abscess and made a free incision, allowing the escape of about a wine-glass of pus. Artificial respiration and cold water affusion soon restored animation, and the case afterward went on to complete recovery.

CAUSALGIA.

DR. C. T. POORE related a case with the following history: A married lady fell in August last, turning her foot inward, and is said to have chipped off the external malleolus. A plaster-of-Paris dressing was applied, and after four weeks it was removed, and she was allowed to go about. She has ever since

had some pain about the ankle. About the first of January she begun to experience a burning pain on the plantar aspect of foot, corresponding to the distribution of the external plantar nerve. This has gradually increased, and when at its height is accompanied by shooting pain in the foot, extending up the leg; swelling and redness on the under aspect of the foot in that location. The pain is brought on by wearing a boot and allowing the foot to hang down. It is absent, or nearly so, when she wears a slipper. There is some slight tenderness over the posterior tibial nerve, behind the internal malleolus, but pressure on this nerve does not cause the peculiar burning pain. There is also twitching of the toes when the pain is intense. There has never been any eruption or glazing of the skin, nor any change in the condition of the nails.

Dr. Post had met with a number of cases of painful affection of the foot, the cause of which had been entirely unknown. There was increased sensibility upon pressure, and certain spots were excessively sensitive. In some of them he had afforded relief by the hypodermic injection of chloroform, in others, by the use of the actual cautery, but some of them had been obstinate.

Dr. Weir asked if Dr. Post could recall what particular spots on the foot were chiefly affected.

Dr. Post answered, the heel, the side of the foot, the anterior part, and, in some cases, the dorsal surface.

Dr. Weir had seen cases in which a painful spot existed between the fourth and fifth metatarsal bones, at the distal ends. According to Mitchel and Morton, the pain in such cases is due to pressure of the fifth metatarsal bone upon the nerve which lies between it and the adjacent bone. He had excised the head of the fourth metatarsal bone in two cases, with the result of affording immediate relief from all pain.

Dr. Yale had seen a case in the wards of the late Dr. Mason almost precisely like that related by Dr. Poore, and in which relief was afforded by excision. He had also seen a case in which the pain originated between the two extremities of the plantar fascia.

HERNIOTOMY.

Dr. E. L. Keyes reported a case with the following history: A young man entered his service at Bellevue Hospital with an exceedingly solid, tense hernial tumor on the right side, which his house surgeon had tried to reduce under ether, without success. The patient said that his hernia had been gradually increasing in size ever since he was a boy, but that he could always reduce it at will. On the following morning Dr. Keyes cut down upon it, found a very solid white mass, which was so firmly attached as to require dissection to liberate its adhesions from the sac. A number of bleeding points were ligated with catgut, cut short, and the whole oozing surface was freely touched with a red-hot Paquelin cautery. A strangulated piece of small intestine, two or three inches long, was found posteriorly. There was very little fluid in the sac. The hard mass had been incarcerated, but it was not a congenital hernia, since the tunica vaginalis did not communicate with the sac, and consisted of large intestine, as proved by its connection above, although it was apparently completely solid. He reduced the entire mass after serious deliberation. He feared to leave it out, because the patient had been on a prolonged spree, and delirium tremens was to be expected. The enlarged internal ring, after reduction, remained sufficiently patulous to admit three fingers abreast. This was closed with deep sutures. The wound was treated antiseptically. Within twenty-four hours the patient had an attack of delirium tremens, requiring a strait-jacket for a week. Localized peritonitis developed under the right hypochondrium, which went on to suppuration. A deep abscess was opened about midway between the anterior superior spinous process of the ilium and the border of the ribs. Pus was abundant but laudable. Dr. Keyes thought it originated in localized suppurative peritonitis. The patient made a perfect recovery, with his hernia radically cured.

The Society then proceeded to the transaction of miscellaneous business.

THE ELEVENTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, May 31 *and June* 1 *and* 2, 1882.

Professor Langenbeck, President.

(Special Report for The Medical Record.)

Many of the most eminent of German surgeons were present, including Billroth, Esmarch, Thiersch, Volkmann, etc.

The scientific work began with a paper by Von Bergmann, of Würzberg, upon the

BLOOD-CHANGES IN ACUTE INFECTIOUS DISEASES.

He claimed that some infectious diseases are produced by organized parasitic bodies; others by unorganized, soluble ferments, similar in nature to pepsin, trypsin, etc. Bergmann further averred that these infecting agents acted upon the white corpuscles of the blood, destroying or dissolving them. This caused a thickening of the blood and an increased tendency to coagulation, facts which explained the capillary thrombosis, especially in the lungs and intestine, with resulting inflammations.

Herr Braun, of Heidelberg, read a paper upon

MALIGNANT STRUMA,

in which he referred to the difficulties of removing excessively large and malignant swellings, especially in the neck. Herr Braun also read a paper upon "Ligaturing the Femoral Vein near Poupart's Ligament." He had found that it could be done without necessarily stopping the circulation in the extremity.

Schwalbe, of Magdeburg, read an article upon

THE RADICAL CURE OF HERNIA.

The author used an injection of seventy per cent. of alcohol in the neighborhood of the hernial sac. This method he considered entirely harmless and very effective. He reported a number of successful cases. Sometimes many injections had to be made, and in one instance the number reached was 150. Schwalbe referred to the American (Heaton's) method of injecting an oak-bark solution. His own method is evidently an imitation of this. He thought the oak-bark less useful, however, than alcohol, on account of its slighter power of diffusion.

In the discussion, Ranke said that he had obtained good results in children, but had had less satisfaction in older cases.

Gussenbauer had used the method in six cases, but it was too early for him to draw conclusions regarding it.

MIKULICZ, of Vienna, read a paper upon

GASTROSCOPY AND ŒSOPHAGOSCOPY,

with demonstration upon a living subject. He gave a description of the instrument and of the difficulties to be encountered in its use. The accumulation of mucus and saliva was prevented by laying the patient on his side. The retching, vomiting, etc., could be prevented by morphia narcosis. With the help of the instrument, Mikulicz had been able to diagnose easily the presence and character of foreign bodies in the œsophagus, also the presence of cancer there. He had found that the upper part of the œsophagus was a closed tube; the lower part, including the cardia, was open. He had discovered five or six cases of a tubular dilatation of the œsophagus to the size of the arm, due probably to an obstruction at the cardia. In certain positions the beat of the aorta can be felt, and the author thought that the instrument would be useful in diagnosing aneurisms of that vessel.

In the discussion, NITZE and GUSSENBAUER deprecated the use of the instrument. The latter related the case of a patient in whom it had injured the gastric mucous membrane dangerously.

LANENSTEIN, of Hamburg, showed a

RESECTED PYLORUS.

The patient had had a gastric ulcer, with great thickening of the walls. Death followed the operation.

RYDIGIÈR, of Culm, showed another resected pylorus for gastric ulcer. The patient in this case lived. The case has been reported in THE RECORD.

TAUBER, of Warschau, read a paper upon the

CHANGES OF THE INTESTINE IN A LONG-STANDING ARTIFICIAL ANUS.

The case showed that an almost entire closure of the intestine had gradually taken place.

SCHEDE, of Hamburg, read a paper upon the

TREATMENT OF GENU VALGUM.

He discussed the relative merits of cutting and bloodless operations, preferring the former for older patients. The author especially recommended the method, as yet little used, of "osteoplasty," or fracturing the bones. Two years before he had first tried it in a very severe case of genu valgum, with surprisingly good results. Since then he had constantly employed it with unvaryingly good results. He had fractured the femur thirty-three times and the tibia thirteen times. In eight days after these operations the child can stand; in four to eight weeks healing is perfect. The bones can be broken with the hands. The limits of age in which this operation applies are two and five years. In older cases Schede recommends osteotomy.

In the discussion, MIKULICZ referred to the difficulties and disadvantages of ordinary apparatus, and commended Schede's method in young children.

SONNENBURG, of Berlin, described an apparatus which drew the limb into proper shape, and said that he had treated his cases very successfully with it.

WINIWARTER had in the past five years used torsion, and he had often produced a double fracture of tibia or femur at one sitting. The cases healed easily.

BIDDER discussed the etiology of the deformity and thought it was often brought about or increased by the way in which the infant was carried, either *always* upon the left or upon the right arm. The knee was thus pressed into the angle between the thorax and abdomen and deformity produced.

SONNENBURG, of Berlin, read a paper

UPON THE USE OF PERMANENT BATHS IN THE TREATMENT OF SURGICAL DISEASES.

This method of treatment had been in use for about a year in the Surgical Department of the Royal University Hospital as well as in the Jewish Hospital. An apparatus is made by which the affected part is kept constantly in warm water of a steady temperature. The water continually flows off and is renewed. The advantages are: pain disappears entirely, the fever falls, the wound secretions are lessened and carried away, the duration of healing is shortened; complications do not occur. The method is applicable in a wide range of cases, but especially when there are large cavities or surfaces, as in the neighborhood of the pelvis, in operations about the rectum, uterus, bladder, and peritoneal cavity. It is particularly useful in cases of profuse suppuration, chronic caries, in lithotomy, and in resections, fistulæ from joint diseases, etc.

In the discussion HAGEDORN, of Magdeburg, said that he had used permanent baths for twenty years in all lithotomies, and with good results. He also had used them in extensive burns and phlegmons. A temperature below 30° R. soon becomes unpleasant to the patient.

SCHEDE had used the permanent baths for six years quite extensively, but he reserved them rather for chronic cases. Thus a woman seventy years old had a compound fracture of the leg. She speedily developed bed-sores, and would undoubtedly have died but for the baths. She was kept in a bath for ten months, when she was cured. The permanent bath is a form of antiseptic treatment often useful when other means fail or cannot be applied.

SONNENBURG said that the temperature of the water may be varied. Some patients preferred it cooler than others. The age of the patient was no contra-indication; the duration could also be very long.

BARDELEVEN referred to Weber's use of salt in the water, in order to diminish the activity of the granulating process. He had himself added thymol (1 to 1,000) to secure an antiseptic effect.

HERR KÜMMELL, of Hamburg, read a description of a

NEW METHOD OF TREATING WOUNDS AND THE USE OF CORROSIVE SUBLIMATE IN SURGERY.

The attempts to get all the advantages of a perfectly antiseptic dressing, with the simplest methods, had led to many experiments. The iodoform dressing had become very popular, but, in Kümmell's opinion, its era was past.

An excellent dressing was a mixture of heated charcoal with clay, in the proportion of 1 to 7. It possessed not only great disinfecting but powerful absorbing properties. The first dressing can be left on for one or two weeks, and there is no inflammatory reaction or disturbance. The substance is especially good in large cavities, as after operations near the rectum. The powder sticks so closely to the surface that it is not easily washed away. In eight or ten days it may be removed and the wound dressed with basilicon ointment.

The above dressing, however, the author found to be dirty and to have some disadvantages. He therefore experimented with corrosive sublimate. It is known

that solutions of this, of the strength of 1 to 1,000, destroy bacteria. Kümmell used solutions of the strength of 1 to 2,000, washing the wound with it. Instruments, catgut, and dressings are disinfected completely by soaking twelve hours in a 1 per cent. solution. Kümmell also used as a wound-dressing fine quartz sand, heated, and then disinfected with a solution of sublimate. This seemed especially advantageous for primary healing. He also used fine spun glass, or

GLASS-WOOL,

and considered it useful on account of its draining property. The fine threads of glass lying together acted as capillary tubes. The wound-surface could also be examined to some extent through the transparent dressing. There is no irritation from this substance, and primary intention occurs very certainly. Herniotomies under this treatment have got well in five to eight days, necrotomies in fourteen days. Either the sand or the glass-wool method is very simple.

(To be continued.)

Correspondence.

DR. TRAILL GREEN AND THE ERUPTIVE DISEASES OF CHILDHOOD.

To the Editor of The Medical Record.

Sir: The essay on "Medicine and Something More," which I read before the late meeting of the Medical Society of Pennsylvania, of which brief mention was made in The Record, was prepared to call the attention of the society to the duty of instructing the laity on various subjects connected with health and peace of mind with reference to disease, as well as to prescribe medicine. In the last number of The Record I read an article on measles, the author of which expressed himself as greatly pained by reading the brief notice referred to above. It would seem to be unnecessary to offer relief to him, as in the next paragraph of his article he says: "I am ready to grant that Dr. Green has good authority for making such statements," and he quotes Dr. Thomas, in "Ziemssen," Trousseau, and others, bringing forward a large amount of evidence which I had not seen, or which I had forgotten if I had seen it. What I wrote was based on my own observation, and I thought the subject worthy of the consideration of the profession.

I copy here that part of the essay which may have been misunderstood. I hope Dr. Gibney and other friends will not charge me as guilty of professional heresy after they have read this extract from the essay:

"I have observed that there has been a growing fear of diseases which we thought, not many years ago, were not of a serious character. I refer to the diseases of childhood, and especially to those of the eruptive class. Here is an instance in point: A young lady was in attendance as a pupil in a boarding school in one of our cities, and there had an attack of chicken-pox. She was isolated from the other members of the household, and no one was permitted to see her but the matron. The young lady was so lonely, separated as she was from all her companions, that she wrote to her father, who instantly ordered her home; and she returned, performing the journey without inconvenience, but not without expense and interruption of study, which was more serious. A physician had not been called to see her at her school-house.

"Now, I would ask, Is it not shameful at this time in the nineteenth century an intelligent lady, having charge of a school for the education of girls, should subject a scholar to solitary confinement because of an attack of varicella? What could she have learned from a physician, in her girlhood home, of the character of this trifling disease? What was impressed upon the minds of the young women gathered in this school who are to preside in homes in their womanhood? Might not this intelligent teacher have supposed that a very large number of her pupils must have had chicken-pox, and that the remainder of them would not have been seriously hurt if they had taken the disease?

"Rubeola we see treated by mothers without the help of a physician, and all that is needed in many cases that we are called to see is a mild, cooling treatment; and yet we meet with individuals now and then who are greatly alarmed when an epidemic of this disease occurs. I shall never forget a visit to a man in bed ill of measles, with all the bedding of winter weather over him, and a thick winter suit of clothes on him from head to feet, his thick winter coat buttoned over his chest, and a thick woollen scarf around his neck. He was as hot as a man could be, and in piteous tones he said: 'Doctor, I am afraid I shall take cold!' I ordered him out of bed, commanded him to take off his day garments, and go to bed as a sensible man should, in his bed-garments. He was living when I last heard of him.

"Some years ago as an epidemic of measles was passing over the community in which I live, I was asked by an intelligent woman, the mother of three children, whether I thought she would be affected by the disease. I said to her that I had not the least doubt of it. She replied, 'You are a good comforter.' I said, 'Madam, in this epidemic every one who has not had the disease is attacked by it.' I had observed it, and I told her what I knew was true. In a short time her children had the disease, and very soon she was in her bed with it, sick almost unto death.

"This woman's mother had for years been in bondage from fear of measles. She took special care to keep her daughter from associating with children who had this disease, and, I believe, took such care of her as to shut her within doors when it was prevailing. I never saw a case like hers. She was sick for weeks, was greatly reduced in strength and flesh, and just escaped with her life. On one of my visits, when she was convalescent, she said to me, 'Doctor, Congress ought to pass a law that no woman shall be allowed to marry until she has had the measles.' I have no doubt she thought her mother a very silly woman, so far as her views of measles were concerned. An attack in childhood would, most probably, have been mild, and before she reached adult life would have been forgotten.[1]

"I believe these diseases help to establish good health. I doubt not you have seen children who did not grow well, who were feeble, who would after an attack of one of the eruptive diseases of childhood commence to grow, and soon become strong and healthy persons.

"In relation to small-pox, and the sure protection which we have in vaccination, it must be ad-

[1] The comparative mildness of the disease as it occurs in childhood is well known.

mitted that we do not give instruction as we should to the families we visit, or that we have no influence over them as medical men. Why is it that there is so much doubt as to the protection which we know is afforded by vaccination? Why should a vaccinated community become so thoroughly demoralized when a case of small-pox appears in it? The only answer we can give is this, we have not instructed the people.

"In the report of Northampton County, presented to this meeting of the society, I have given my experience relative to vaccination, and I will not repeat what I have written in that report. I will only say in this connection that in a practice reaching through almost fifty years, I have not seen a case of small-pox or of varioloid in any person vaccinated by myself. I have, in all the families I have attended, been careful to see that the vaccination was successful, and among them all I do not know an individual who would object to being revaccinated or refuse vaccination to a child."

Thus far the extract from the essay.

I see no call for a disclaimer, and I would not blot a word which I have written. Dr. Gibney sustains my position in what he says as quoted above; indeed, many of the cases he cites prove more than my observation justified me in attempting to prove.

Furthermore, Dr. Gibney admits that the disease, as it appears in the rural districts, differs from the disease as it occurs in cities. With us, as already stated, the disease in many cases is so mild that the mothers of the children safely conduct the whole treatment. I have never seen a case of diseased bones or joints which I could trace to measles as a cause; and it must be remembered that every one, sooner or later, has an attack of measles. It is quite easy, therefore, to say that this or that disease followed an attack of measles; but it is not so easy to determine how far the eruptive disease acted as the exciting cause. We should ask: Do not these diseases occur after various other diseases? Do they not occur when children have not had any of the peculiar diseases of childhood? The crowded tenement houses of cities certainly furnish cases of disease, in scrofulous children, which cannot be traced to any cause save the bad air, poor food, and general unfavorable hygienic surroundings.

I find but one record of death from measles in my notes of a long practice, and this occurred in an out-patient of the Fifth Street Dispensary, Philadelphia, an institution with which I was connected in the first year of my practice. The child was attended in a home such as the cities furnish to the poor. I was young in my professional life, but I had the assistance of the late Dr. Hugh L. Hodge, who was one of the consulting physicians of the dispensary. This case occurred in the early summer, when the narrow streets and crowded houses of the poor do not aid us in our work. I have seen many epidemics of measles since, and I record my testimony as to the mildness and usually favorable termination of measles in the rural districts and healthy towns.

TRAILL GREEN.

DEATH DURING SOMNAMBULISM.—Lieut. Child, of the British Navy, jumped overboard in a sleep-walking state, recently, and was drowned. He dreamed, it is supposed, that he heard the cry of "man overboard," and rushed upon deck at once to save a comrade.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 9, 1882, to July 15, 1882.

GREENLEAF, C. R., Major and Surgeon, now awaiting orders, to report in person to the Commanding Officer, Columbus Barracks, Ohio, for duty as Post-Surgeon at that post. S. O. 160, A. G. O., July 12, 1882.

FORWOOD, WM. H., Major and Surgeon. To report in person to the Lieutenant-General at Fort Washakie, Wyo., on or about July 23, 1882, for duty as Surgeon and Naturalist, on the tour of inspection and exploration to be made by the Secretary of War and the Lieutenant-General. S. O. 70, Department of the Platte, July 6, 1882.

BROOKE, JOHN, Capt. and Asst. Surgeon. Having reported at these Headquarters, is assigned to duty as Post Surgeon at Angel Island, California. S. O. 120, Military Division of the Pacific and Department of California, July 7, 1882.

GIRARD, J. B., Capt. and Asst. Surgeon. Relieved from duty at Fort Grant, A. T., and assigned to duty at Fort Lowell, A. T. S. O. 106, Department of Arizona, July 3, 1882.

BYRNE, C. B., Capt. and Asst. Surgeon (Fort Barrancas, Fla.). Granted leave of absence for one month, with permission to leave the Department and to apply for an extension of two months. S. O. 68, Department of the South, July 12, 1882.

HAVARD, VALERY, Capt. and Asst. Surgeon. Relieved from temporary duty at these Headquarters, and at post of San Antonio, and assigned to duty as Post-Surgeon at Fort Duncan, Tex. S. O. 68, Department of Texas, July 5, 1882.

FINLEY, J. A., Capt. and Asst. Surgeon. Assigned to duty as Post-Surgeon at Fort Concho, Texas (Fort McKavett abandoned). S. O. 68, C. S., Department of Texas.

BARNETT, RICHARDS, Capt. and Asst. Surgeon. To accompany the Brigadier-General commanding on his journey to Forts Boidger, Wyo., and Thornburgh, Utah. S. O. 70, Department of the Platte, July 6, 1882.

POWELL, J. A., First Lieut. and Asst. Surgeon. To report to the Commanding Officer, Fort Davis, Tex. for duty (Fort Stockton, Tex., abandoned). S. O. 68, C. S., Department of Texas.

GORGAS, W. C., First Lieut. and Asst. Surgeon. When relieved by Asst. Surgeon Havard, to report to the Commanding Officer, Fort Brown, Tex., for duty. S. O. 68, C. S., Department of Texas.

AN UNHAPPY MISTAKE.—A very sad case is reported from Waukesha. Wisconsin. Dr. Hugo Philler, who is said to be an aged and most trustworthy and experienced physician, administered a dose of morphine to Mrs. Magdalena Hille by mistake for quinine, and caused her death. Dr. Philler had been out all night and was exhausted by want of sleep. He discovered the mistake, and hurriedly ordered his team, procured a stomach-pump and antidotes, and drove as fast as he could to the Hille residence. The time of his arrival was about fifty minutes after the morphine had been administered. He used the stomach-pump and applied his best art, but Mrs. Hille was beyond all help, and died soon after.

Medical Items and News.

Contagious Diseases — Weekly Statement. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending July 15, 1882.

July 15, 1882.	0	7	20	2	31	53	5	0

Erratum.—The article under caption "Hæmatemesis" in The Medical Record for July 8th, page 38, ninth line from top, for "relaxation" read "ulceration."

The Prize of the New Jersey State Society.—The subject for the essays to be offered in competition for the Fellows' Prize, for the coming year, is "The Importance of Exploration of the Urine, Chemical and Microscopic, as an Aid to Practice; and the Relation of *Albuminuria* to Diseased Processes." In a recent notice the word *hæmaturia* was used instead of albuminuria, by our correspondent.

Preserving Bodies by "Galvanoplasty."—At a recent meeting of the Physical Society, Berlin, Prof. Christiani exhibited as samples of a new method of preservation a series of organic bodies coated galvanoplastically. A mulberry leaf, a crab, a butterfly, a beetle, the brain of a rabbit, a rosebud, and other objects were plated with silver, gold, or copper, and showed all details of their outer form, down to the finest shadings. As to the process, it was stated that the objects to be preserved being put into a solution of silver nitrate in alcohol, then dried and treated with sulphuretted and phosphuretted hydrogen form good conductors, which, brought in the usual way into the galvanoplastic bath, can be coated with any desired thickness of a metallic deposit.

Artificial Quinia.—It is announced, in a recent number of the *Comptes Réndus* of the French Academy, that Mr. E. J. Maumené has succeeded in the synthesis of quinia by a simple and easy process, and that he has deposited with the Academy a sealed package, describing his process and containing a specimen of the artificial alkaloid. Therapeutic experiments with the artificial substance are still unfinished, but very soon the alleged discoverer will publish detailed statements and evidences of his results.—*Ephemeris of Materia Medica, etc.*

Mr. T. M. Balfour has been elected to the new Professorship of Morphology in the University of Cambridge. Mr. Balfour is a young man, having taken his degree through the Natural Sciences Tripos in 1873.

The Hypodermic Administration of Amyl Nitrite.—Mr. J. J. Frederic Barnes reports favorably (*British Medical Journal*) upon the use of amyl nitrite. He injects fifteen minims of a ten per cent. solution, equivalent to one minim of the pure drug. In cases where respiration is weak or suspended, it brings on immediate cardiac action. In acute lumbago a single injection relieves the pain like magic. In colic it also acts very well. The physiological effect is the same as when administered in the ordinary way.

Cutting down Insane Asylum Expenses.—The Governor has vetoed items in the appropriation bill for various asylums, distributed as follows: Auburn Insane Aylum, $8,000; Binghamton Insane Asylum, $20,000; Hudson River Asylum, $15,000; Buffalo Insane Asylum, $4,900; Homœopathic Asylum, $14,500; Utica Asylum, $15,029.38. This makes a total of $69,429.38 saved. The reasons given are that the sums appropriated were too large, or were for objects that should have been covered by the maintenance fund.

The Safest Anæsthetic Known.—Dr. Richardson says that methyline bichloride, ten fluid drachms, and absolute methylic alcohol, six fluid drachms, constitute the safest known anæsthetic when the methylic alcohol is absolutely pure.—*Lancet.*

The Committee on First Aid to the Injured has just issued its first report of operations. This report shows that 132 out of 190 students have received certificates entitling them to act as qualified assistants to the injured in any emergency. During the first season eighteen free classes have been established in this city among shop-girls, women living in tenement-houses, and among the members of working-men's clubs. It is in instructing the employees of factories, where the workers are exposed to danger by reason of contact with intricate machinery, that the committee have put forth most effort. Some effort was made to instruct railway employees at the Grand Central Depot, but the attempt was retarded greatly by the difficulty experienced in getting the men together for any specified time. No effort has yet been made in the direction of enlightening members of the police force in the matter of aiding the injured, but the committee report that the Police Superintendent has shown an interest in the work, and has favored a thirty days' course of instruction under the committee's supervision as an obligatory preparation for qualification for appointment on the police force. The committee announce that in the fall they will endeavor to have the course of special instruction introduced and followed in the Fire Department as well as among the police.

The report from which we condense the above presents its side of the case very fairly. It should be added that these societies have been organized of late in Berlin and other places in Germany. They go by the name of Good Samaritan Societies and have become fashionable and popular. They are considered, however, by some of the medical profession there as useless and a nuisance.

The California State Medical Society had an unusually successful meeting in April last. A number of reports on medical progress were read. The subjects of carrying out the medical registration law, of the necessity of an asylum for insane criminals, and of medical education were discussed. Professor Rudolph Virchow was elected honorary member. The following officers were elected for the ensuing year: *President*—L. C. Lane, San Francisco; *First Vice-President*—Ira E. Oatman; *Second Vice-President*—Wm. E. Taylor; *Third Vice-President*—E. A. Stockton; *Fourth Vice-President*—H. J. Crumpton; *Treasurer*—Ira E. Oatman, Sacramento; *Permanent Secretary*—Wallace A. Briggs, Sacramento.

THE OHIO STATE MEDICAL SOCIETY met June 13th, at Columbus, with President Dr. Starling Loving in the chair and Dr. J. F. Baldwin at the secretary's desk. Dr. H. G. Landis read a paper on the "Progress of Obstetrics and Gynecology;" Dr. R. A. Vance read a paper on the "Surgery of the Arteries," and Dr. D. N. Kinsman a paper on the "Etiology of Consumption." Each of the papers were in turn discussed by the members. In the evening Prof. Edward Orton, of the Ohio State University, delivered a lecture on the "Relation of the State to Public Health." The Society, at its conclusion, ordered the publication of one thousand extra copies.

Wednesday morning papers were read by Drs. N. P. Dandridge, P. S. Conner, and Sidney Norton. In the afternoon, amendments to the Constitution were adopted, without an anticipated wrangle. Papers were read by Drs. S. C. Ayres, W. H. Mussey, and Philip Zenner. The papers were all fully discussed. The election of officers for the ensuing year and the appointment of committees took place at two o'clock. Dr. C. P. Landon, of Westerville, was elected President, and Dr. George A. Collamore, of Toledo, Secretary. Dr. J. R. Black, of Newark, then delivered a lecture on "Preventable Diseases," after which the members were invited to an elegant collation spread for their benefit in the dining-hall. Papers sufficient to occupy the entire time of the Society for the succeeding day were announced

All in all, the meeting, says *The Cincinnati Lancet and Clinic*, was one of the most profitable in the history of the Society.

THE MISSOURI STATE MEDICAL ASSOCIATION held its annual meeting at Hannibal, May 16th, 17th, and 18th. Dr. Willis P. King, of Sedalia, President, in the chair. About one hundred members were present. No important business was done other than routine. Papers were read upon "Railroad Surgery," "Phlegmasia Alba Dolens," "Quacks," by Dr. King, of which two thousand copies were ordered to be printed.

Delegates from the Marion County Medical Association were at first refused admission, because one of the members consulted with homœopaths. The offending member then resigned, whereupon the delegates were admitted. Dr. C. H. Hughes read a paper on "Latent and Unrecognized Diseases of the Nervous System." The subjects of "Hydrophobia," "Laryngitis," and "Vaccination" were also brought up.

Dr. A. E. Gore, of Paris, was elected President for the ensuing year; Drs. C. A. Todd, of St. Louis, and J. H. Duncan, of Columbia, Recording Secretaries; Dr. William Dickinson, of St. Louis, Corresponding Secretary; Dr. C. A. Thompson, Treasurer.

SEMI-ANNUAL MEETING OF VERMONT STATE MEDICAL SOCIETY.—The semi-annual meeting of the Vermont State Medical Society, held in Burlington June 8th and 9th, attracted a large attendance of physicians from all parts of the State. At the first morning session Dr. Conland, of Brattleboro, read a paper on "Advancement of Medical Practice During the Past Year." In the afternoon, Dr. J. S. Richmond, of Woodstock, read a paper on "Ethics." Dr. Butler offered a resolution condemning the New York Code, which was adopted. A paper on "Urinary Analysis," by Dr. J. H. Linsley, was read. Dr. Linsley's paper was accompanied by numerous and instructive tests, with chemical apparatus, for the detection of the presence of sugar and albumen in diseased urine. Dr. Linsley's experiments were well received. An address was delivered by the Vice-President, C. W. B. Kidder. In the evening a social reception took place at the residence of Dr. L. M. Brigham.

On the second day, Prof. A. T. A. King read a paper on "The Ring of Bandel."

A "Report of Progress in Surgery" was read by Dr. John B. Wheeler, of Burlington. It was devoted particularly to an explanation of improved methods of performing operations and of treating wounds, and to remarks upon the modifications which the antiseptic treatment of wounds has undergone within the past few years.

Dr. F. G. Mills, of South Royalton, Dr. C. P. House, of Royalton, and Dr. L. McMillan, of Barnard, were elected to membership in the Association.

OPERATION FOR BILIARY FISTULA.—Dr. A. Von Winiwarter, Professor of Surgery in the University of Lüttich, Belgium, has recently operated for a biliary fistula in a case of impermeable ductus choledochus. The operation was successful and the patient is now in good health.

A NEW RUSSIAN MEDICAL SOCIETY has recently been organized, composed of the prominent medical men in St. Petersburg and Moscow. The object is to unite the profession more closely and secure its advancement.

THE UNVEILING OF A STATUE TO VON GRAEFE took place with much ceremony at Berlin, May 22d. Profs. Helmholtz, Donders, Virchow, Dubois Reymond, and others were present. Profs. Langenbeck and Artl made appropriate speeches. The statue is said to be a very handsome one.

THE THERAPEUTIC USE OF MIRACLES.—M. Féréol (*Journal de Médicine de Paris*) relates the case of a young girl affected with an incessant hysterical cough which was very distressing, and obstinately resisted all remedies. One day he noticed in her room a bottle of water from the famous holy well in the Pyrenees, and it occurred to him that this was a case in which a cure might be obtained. In an interview with the girl's mother he explained his views, she acceded to them, the pilgrimage was taken and a cure resulted. M. Féréol remarked with reference to this, that the supernatural does not exist, all that is is natural; there are, doubtless, many things we do not understand, and we cannot deny that so-called miraculous cures take place under the powerful modifying influences of moral or mental impressions. He thought it better to recognize these facts and keep a control over our patients than to ignore them, with the result that the same means are used without us.

A GREAT PRIZE.—The Royal Academy of Medicine of Belgium offers the tempting sum of 8,000 francs for a sufficiently worthy essay elucidating by clinical facts, and if need be by experiments, the pathogenesis and therapeutics of diseases of the nervous system, and especially of epilepsy. The essays must be handed in by December 31, 1883. A sum of from 300 to 1,000 francs will be given to any author whose essay, while not meriting the prize, deserves some recompense.

The sum of 25,000 francs will be given to any one who makes any epochal progress in the therapeutics of diseases of the nervous system, such as a discovery of a remedy for epilepsy.

Original Communications.

THE MECHANICAL EFFECT OF NERVE-STRETCHING UPON THE SPINAL CORD.[1]

By C. L. DANA, A.M., M.D.,

PHYSICIAN TO CLASS OF NERVOUS DISEASES, NORTHEASTERN DISPENSARY; MEMBER OF THE AMERICAN NEUROLOGICAL ASSOCIATION, ETC.

The spinal cord hangs rather loosely in its canal. It changes its position in the different movements of the trunk. The question in nerve-stretching, therefore, is essentially not whether the cord moves, but whether it is stretched.

The spinal cord is quite firmly connected with the dura mater. This is fastened to the borders of the foramen magnum; below it extends over the nerve-root into the intervertebral canals, and is continuous with the nerve-sheaths.

In pulling on the sciatic nerve the traction comes on the cord and dura together, but chiefly on the latter. This I have demonstrated to my own satisfaction, at least, in the following way. I exposed the sacral, lumbar, and part of the dorsal canal. I then cut through the dura for a short distance transversely before and behind. I finally cut the cord entirely across, leaving two lateral bands of the dura untouched. By pulling on the sciatic both cord and dura above the section were moved. By very forcible pulling I drew one of the branches of the cauda equina, with its investing membrane, entirely through the intervertebral canal. It is a fair inference from this and other facts that the idea, put forth by some, that by opening the nerve-sheath and pulling on the nerve alone we can move the cord and not its membranes, is quite erroneous.

The factors which prevent the traction on a nerve from moving the cord are these: 1st. The union of the nerve to its sheath and of that to the surrounding soft tissues. 2d. The union of the sheath to the wall of the intervertebral canal. Here the nerve makes an angle also, and force is thus lost. The union in the canal may be very firm; and it is here that the strongest opposition is found. 3d. The extensile character of the nerve itself.

Once the force has reached the spinal canal, its influence must be to stretch the cord; for this organ and its membranes are yielding and elastic,[2] and, as has been said, are fastened quite firmly at the top.

As to whether the cord is stretched when the sciatic, crural, or brachial nerves are pulled upon, the evidence is of two kinds: 1st, anatomical, and, 2d, clinical. Regarding the first I find the following:

1. Harless & Huber,[3] also Conrad,[4] are cited by Chauvel as stating that the cord is not moved by pulling on the nerves. I could not get access to the original papers of these gentlemen, and must let their evidence go.

2. Vogt[1] states that the cord is not moved. He performed experiments upon two subjects. In the first he pulled upon the sciatic and failed to move the cord, but he did not open the dura. This I believe to be of no importance. In the second case he stretched the brachial plexus, also with no result.

3. The Brothers Fieber[2] saw the cord move upon very forcibly flexing the thigh, the knee being extended. They had previously exposed the sciatic nerve.

4. Gillette[3] asserts that on powerfully stretching the sciatic he felt the medulla move. This experiment was not very carefully conducted, however.

5. Höslin & Lohlein are cited by Braun[4] as seeing the dura move on stretching the sciatic. On opening the dura, however, they could not see the cord move.

6. J. Symington[5] states that in traction on the sciatic the cord is not moved, but that the dura mater is. All the force is, he thinks, expended upon the dura. He refers in a general way only to his dissections and experiments, and his assertions are weakened on this account.

7. Gussenbauer[6] saw the cord move upon stretching the sciatic. In the lumbar region the amount of movement was from two to three millimetres. He split open the dura first. He also saw the medulla move.

8. By far the most careful experiments have been made by Dr. J. Braun.[7] This observer used an instrument for measuring the amount of movement. He laid open the spinal canal to the foramen magnum, and split open the dura. He also measured the amount of traction used. He found that the cord moved different amounts at different heights; thus:

At the lumbar region—				
With	1 lb.	pull it moved	0.04	millimetres.
"	10 lb.	" "	0.66	"
"	30 lb.	" "	0.83	"
"	60 lb.	" "	2.00	"
At tenth dorsal—				
With	1 lb.	pull it moved	0.04	"
"	60 lb.	" "	1.75	"
At eighth dorsal—				
With	1 lb.	pull it moved	0.04	"
"	60 lb.	" "	1.17	"
At fifth dorsal—				
With	1 lb.	pull it moved	0.33	"
"	60 lb.	" "	0.05	"
At first dorsal—				
With	1 lb.	pull it moved	0.16	"
"	60 lb.	" "	0.33	"

He could not measure the movement in the cervical region, but he states that it could be traced up to the foramen magnum, and he is confident that the medulla must have been moved. It will be seen that, according to this observer, while the cord moves about $\frac{1}{12}$ inch in the lumbar region, it moves but $\frac{1}{25}$ inch at the first dorsal. The cord is, therefore, stretched.

It should be added that he got the foregoing results upon two cadavers. Upon a *third* with which he experimented *no movement could be seen.*

---

[1] Read at the annual meeting of the American Neurological Association, June 21, 22, 23, 1882.

[2] I measured the elasticity of the cord in the following way: I took the lower fragment of the spinal cord of a cat, stripped it of the dura mater, and suspended it against a wall. The part suspended and stretched measured two inches and three-eighths. The transverse measurement was one-fourth of an inch in most of the extent. By pulling on the lower end the fragment was extended five thirty-seconds of an inch. On removing traction it returned to the normal length. On traction of more than five thirty-seconds of an inch it failed to return, and was evidently somewhat torn.

I should estimate that the spinal cord as a whole could be stretched about one-twelfth to one-fifteenth of its length, or somewhat over an inch.

[7] Loc. cit.

9. I have experimented—

(*a*) Upon a twelve pound dog.[1] The cord was exposed and over fifty pounds traction made upon the sciatics. No movement could be detected. The dura was slit, and lastly the whole cord was cut across, but still with no result.

(*b*) Upon a human cadaver.[1] The subject was a man weighing over one hundred and eighty pounds, dead about two days. The skull-cap and brain were removed and the medulla exposed. Traction of over one hundred and fifty pounds was made upon the left sciatic, but the medulla did not move. The nerve was finally broken in pulling. The right sciatic was tried with the same result. Dr. Wm. H. Porter was present and confirmed the opinion that no motion took place.

(*c*) The medulla and sciatic nerve of a dromedary weighing about four hundred pounds were exposed. Traction of over fifty pounds failed to move the medulla.

(*d*) The human cadaver of a man weighing about one hundred and forty pounds was taken, the skull-cap and brain removed; the spinal cord exposed from the second dorsal to the third lumbar vertebra. The subject was placed on the edge of the table, face down. The left extremity was then forcibly flexed upon the trunk, the leg being kept extended. When the extremity passed a right angle with the body, the cord and then the medulla were seen to move. Motion in the medulla did not take place until the limit of flexion was nearly reached. Its movement was very slight, indeed. Great care was taken to exclude error. Dr. Wm. J. Morton, who kindly assisted me in this and the following experiment, agreed that there was a perceptible motion.

The movement of the spinal cord was very marked. It was measured as follows: A small stiff wire, eleven inches long, was flattened at one end and this flat end thrust into the cord. It was rested against a transverse piece of metal two-thirds of an inch above the surface of the cord and fixed in the bony tissue on each side. A movement of the short arm would be magnified not quite fifteen times by the long arm. There was a device for registering the movement of the long arm. It was found that at the level of the first lumbar there was a movement of the cord downward of about $\frac{1}{12}$ in. (1.9 mm.). The cord was also pulled forward. At the level of the sixth dorsal a movement of $\frac{1}{16}$ in. (1.2 mm.).

The sciatic nerve was then exposed and traction applied. A scale balance was used. It was found that a pull of twenty pounds moved the cord perceptibly. A pull of about fifty pounds caused a slight, barely perceptible, movement of the medulla.

The movement of cord on pulling the sciatic was slightly (about one-fourth) less than that obtained by subcutaneous stretching. Comparative experiments were repeatedly made. The exact amount of movement was not recorded. The dura mater was not opened in this experiment; but the substance of the medulla was seen to move, which proved that the whole cord did the same.

(*e*) A second human cadaver of a slightly heavier man was used. The cranial cavity was not opened. The spinal cord was exposed as in the previous case. Flexion of the extremity, as before, caused very marked movement of the cord. This movement, at a level with the eighth dorsal, amounts to $\frac{1}{8}$ in. (3 mm.). Movement higher up was perceptibly less. The sciatic was then exposed and traction made. A pull of one pound caused a movement of the cord. A pull of thirty pounds moved the cord $\frac{1}{10}$ in. (2.5 mm.) at the level of the eighth dorsal vertebra. Comparative experiments showed that here also more movement could be obtained by subcutaneous stretching than by direct traction upon the sciatic. The measurements given were with the dura mater uncut. When it was cut and the stretchings repeated the cord itself was seen to move as the dura had done, though not quite so much. From our experiments it appeared that the traction came most upon the dura mater. This in the lumbar region is pulled down and even thrown into longitudinal folds. We did not in any case open the nerve-sheath of the sciatic.

With regard to the amount of force expended in subcutaneous stretching, I found that by catching the hook of the spring scales into the sciatic within the pelvis, then bracing the large dial surface upon the os innominatum and flexing the leg to a right angle, a force of twenty-five pounds was required to raise the nerve from its bed. When the limb was extended, a pound would raise it easily.

(*f*) I exposed the dorsal part of the cord of a cat. A traction of ten pounds caused something apparently to give way. The cord and dura then moved very perceptibly upon traction of even half a pound.

From the above it will be seen that the experimental evidence as regards stretching the spinal cord, so far as I can find, is as follows:

Cord or Medulla does not Move.	*No. Cases.*	*Cord or Medulla Moves.*	*No. Cases.*
Harless and Huber	?	Bros. Fieber (subcutan. stretching)	1
Valentin and Conrad	?	Gillette (medulla moved)	1
Braun	1	Gussenbauer (saw cord and medulla move)	2
Vogt	1	Braun (saw cord move)	2
Dana (medulla did not move, nor cord in one lower animal)	1	Dana	2
Symington (saw dura move only)	1	" also in lower animal (cat)	1
Hoslin and Lohlim (saw dura move only)	1		

The above figures appear to indicate more than they really should. In all the carefully detailed experiments on the human cadaver, except one of Vogt's and one of Braun's, the cord was seen to move. In one case of mine the medulla did not move.

The *clinical evidence* that stretching the sciatic nerve stretches the spinal cord is confined chiefly to the cases in which the cutting operation is done. I cannot pretend to have collected all, or even much of it. Nor am I sure that all the cases cited are to the point. In the great majority of cases of nerve-stretching no clinical evidence of any mechanical violence to the cord is recorded.

1. Kulenkampff[1] relates a case of tabes, with stretching of the sciatic, a force of eighty to one hundred pounds being used. The patient developed a cystitis at once, and soon died.

2. Gussenbauer[2] relates a case of tabes, with nerve-stretching. Shortly after the operation there were some disturbances of the heart's action, of breathing, and of the pupil. There was, first, a slight improvement, then pyelonephritis and death. On post-mortem two submeningeal hemorrhages were found, 1.5 ctm. long, near the second and third dorsal vertebra. There were also recent inflammatory adhesions between pia and dura.

[1] These experiments have been already reported in THE MEDICAL RECORD, March 4, 1882, p. 243.

[1] Berlin Klinisch. Wochen., No. 48, 1881.

[2] Prog. Med. Woch., March 15, 1882.

3. Westphal[1] relates a case of spastic spinal paralysis, for which nerve-stretching was performed. The result was a flaccid paralysis, then death. Post-mortem showed a focus of softening in the lumbar region, on the side of the stretched nerve. Westphal attributed it to the operation.

4. Westphal[1] also relates a case of stretching the brachial plexus, followed by a meningitis. But Lallemand has shown, by citing a counter case, that this may have been due to the injury to the nerve itself.

5. Israel[1] stretched the sciatics in a case of spastic spinal paralysis. A flaccid paralysis followed, involving muscles of the thigh not supplied by the nerves stretched.

6. Langenbeck's case of supposed tabes is well known. The patient died, it was thought, from chloroform narcosis. It might be queried whether the nerve-stretching was not a factor in the question. It might be added here that Langenbeck's method of stretching the sciatic is to pull upon it until some change is noted in the pupil, heart, or respiration.

7. M. Benedict reports a case of sciatic nerve-stretching. It was followed by severe vomiting, singultus, and paralysis of the bladder.

In connection with the above cases, some of which can be variously interpreted, the fact should be remembered that in the vast majority of instances the symptoms following nerve-stretching are those of interference with the functions of nerve-trunks, and that the efficacy of nerve-stretching has been almost entirely confined to peripheral diseases.

The foregoing refer to the effects following the cutting operation. In *subcutaneous nerve-stretching*, the evidence that any central stretching is produced in the living body is very slight.

1. Gussenbauer[1] had a female patient, aged twenty-three, who had suffered from polyarthritic rheumatism since childhood. There was no heart disease. The knees and hips were flexed and fixed. The ankyloses were forcibly broken up under chloroform. Nine hours later the patient suddenly died.

2. A similar case, also cited by Braun, occurred in Billroth's clinic.

3. Professor Pribram, of Prague, related to Braun[2] the case of a young man with long-standing rheumatic contractures of hips and knees. He was operated upon. Next day he suddenly died, without apparent cause. Post-mortem showed numerous small hemorrhages along both sciatics, in the intervertebral canals, and upon the dura and pia as far as the cervical cord. These hemorrhages were all fresh.

This case is, I think, unique. I have tried to find whether any similar one has occurred in this city. Drs. H. B. Sands, L. H. Sayre, R. F. Weir, G. F. Shrady, H. M. Shaffer, V. P. Gibney, and T. E. Satterthwaite, of whom I have made inquiries, have all informed me that they had had no such experience, nor can I find any in the books.

4. I etherized an epileptic and stretched the sciatics as powerfully as I dared, Dr. G. M. Hammond kindly assisting me. For two weeks subsequently the patient complained of constant tinnitus and dizziness. He was given hydrobromic acid, which relieved him. In the two weeks he had had but one fit. He had previously had one or two every day.

[1] See Report of Debates on Nerve-Stretching, before Berlin Medical Society. Centralbl. f. Chirurg. 17. Jan. 28, and Centralbl. f. Nerolk. Psych. 15 Feb., 1882.

[2] Case cited by Braun, *vide* loc. cit.

From a study of the foregoing facts relative to the mechanical effect of nerve-stretching upon the cord, I come to the following conclusions:

(A) As regards the cutting operation:

1. Traction upon the sciatic nerve of the cadaver in the majority of cases, but not in all, stretches the spinal cord.

2. This stretching is greatest at the lower part, amounting to 2 to 3 mm., with a very powerful pull (50 to 80 lbs.).

3. The movement is distributed over the yielding cord, and only in a *minority of cases* does it reach the medulla. The medulla then moves very slightly, less than 0.3 mm.

4. When the cord is not moved it is due probably to the unusually tight adhesions of the sheath to the nerve, and of that to the surrounding tissue, especially in the intervertebral canal.

5. Traction upon the nerve and sheath if it reaches the spinal canal acts chiefly upon the dura. That is, the cord is stretched partly by direct force, but chiefly by the movement of the enveloping membrane.

(B) As regards subcutaneous nerve-stretching:

1. On the cadaver this is a powerful means of moving the cord.

2. In the living subject it is as yet doubtful if subcutaneous nerve-stretching affects the cord mechanically at all. The clinical evidence is very meagre; anatomical evidence cannot be obtained.[1]

Finally, I would say that I have confined myself to studying the grosser mechanical effects of nerve-stretching. It is, of course, very possible that even when traction does not directly and grossly affect the cord there may yet be central effects produced, reflexly or otherwise.

[1] Vogt, according to Gray, claims to have demonstrated that the most extreme normal movements of the body cannot abnormally stretch normal nerves.—*Journal of Neurology and Psychiatry*, *May*, 1882, p. 216.

THE CITY CHARITABLE INSTITUTIONS.—A census of our city charitable hospitals for the past year shows the following number of patients:

Bellevue Hospital, 680; Charity Hospital, 970; Incurable Hospital, 104; Homœopathic Hospital, 617; Hart's Island Hospital, 247; Randall's Island Hospital, 742; Almshouse Hospital, 120; Maternity Hospital, 48; Infants' Hospital, 200; Workhouse Hospital, 56; Emergency Hospital, 4; Colored Home and Hospital, 50; Emigrant Hospital, 1,200; Riverside Hospital, 70. Total in city hospitals, 5,108.

CASES OF INTESTINAL OBSTRUCTION,[1]

With Remarks on Diagnosis and Treatment.

By CHARLES K. BRIDDON, M.D.,[2]
SURGEON TO COLORED HOME AND HOSPITAL, NEW YORK.

ACUTE INTESTINAL OBSTRUCTION—LAPAROTOMY—DEATH.

Thomas H. S——, aged thirty-five, New York, married, laborer; admitted November 30, 1881, 7 P.M., with following history: This A.M. about 8 o'clock was taken with severe pain in the hypogastrium and with a desire to micturate, but on endeavoring to do so found it impossible. Remained in this condition until just prior to admission, when he sought aid of a neighboring physician, who endeavored, without success, to pass a number of catheters, and sent him to this institution for further treatment. Appropriate means were used to overcome the stricture without avail, and at 10 P.M. aspiration of the bladder above the symphysis pubis was performed, and f ʒ xxi. of urine removed. It was amber in color, cloudy, acid, sp. gr. 1022, and free from albumen or sugar. He was fairly nourished; appetite poor; bowels constipated; tongue clean; pulse, 96; respiration, 32; temperature, 99°. Heart and lungs healthy. During the night he was kept free from pain by liquor morphiæ (U. S. P.) and had an unconscious evacuation of the bladder toward morning. The two following days (December 1st and 2d) he complained of hypogastric pain and dribbling of urine, but there was not any marked distention of the bladder. On the 3d he passed urine twice in small quantity, mixed with stringy mucus. Bowels not having moved, was given magnesiæ sulph., and passed a few scybalous masses. The next evening (4th), no urine having been passed during the day and the bladder being markedly distended, aspiration was again performed in same situation. During the operation, when about f ʒ viii. of blood-stained urine had been withdrawn, the instrument became clogged with mucus and clotted blood, and rendered further removal impossible. The urine was passed in small amounts the two following days (5th and 6th), but on the evening of the 7th the bladder was again found greatly distended and aspiration was necessary for the third time, f ʒ xxii. of clear urine being removed. On the following morning (8th), succeeded in passing No. 4 soft rubber catheter into the bladder and left it *in situ* for six hours, after which was able to introduce the soft French bougies up to No. 17. Patient afterward continued to pass the urine naturally. He now began to complain of attacks of hiccough and vomiting at intervals, and of abdominal pain, which persisted in spite of treatment until the 11th, when the abdomen became slightly tympanitic. The vomiting now became incessant, consisting of food and bile-stained mucus, and on the 12th instant, the abdomen was found to be slightly tender on pressure, markedly distended, and on percussion tympanitic all over. Pulse, 78; respiration, 26; temperature, 99°. These symptoms, with the fact that there had not been a normal evacuation of the bowels, suggested an obstruction of the gut. Was given spirits terebenthinæ, ℥ xx., and enema of same in the afternoon, and during the night passed a small amount of hardened fæces. December 13th, same symptoms continued. Breathing was chiefly thoracic on account of the immobility of the abdominal walls. By digital exploration of rectum a resilient mass, feeling like partially distended gut, could be felt behind and to the left of the bladder and apparently attached to the pelvic wall. Pressure on this was very painful and caused a desire to defecate. Dr. Briddon saw patient at 4.30 P.M., and ordered him put under the influence of ether, and the bowels to be filled with water through a funnel, patient being inverted. Endeavored to do so, but was able to get in only about four pints, when it regurgitated. About 1 A.M. (14th) passed about a quart of water and half a teacupful of small fecal masses. Did not vomit through the night and the tympanites was not so great; pulse, 80; respiration, 28; temperature, 100°. At 2.30 P.M., at a consultation of the surgeons, laparotomy was deemed advisable. Dr. Briddon operating, patient being anæsthetized and with a reliable carbolic acid spray playing over the abdomen, an incision was made between the two recti from immediately below the umbilicus to within an inch of the pubis. The consecutive layers were divided until the peritoneum was exposed, and this was incised upward and downward upon a director; there was no escape of the products of inflammation, and fortunately very little annoyance from intestinal protrusion. On introducing the finger into the cavity, it at once encountered what was supposed to be the cause of trouble, a loop of small intestine adherent to the abdominal wall in the region of Hesselbach's triangle; with some little difficulty a finger was hooked around the loop at the point where it was adherent. To facilitate the separation it was deemed advisable to carry the incision in the abdominal wall as far as possible downward, and in doing this a cavity was opened which discharged a few ounces of fetid pus; means were at once used to prevent any escape of this into the abdominal cavity, the pus cleaned out by the introduction of sponges wrung out of a solution of carbolic acid, and its interior thoroughly explored. It was situate just above the fundus of the bladder, immediately behind the body of the pubis. The cavity was filled temporarily with sponge, and the operation proceeded with. The loop of intestine, which was adherent by a surface, the area of which was about an inch and a quarter in diameter, was gradually and carefully separated, the adhesions were firm and certainly did not look like recent formations. When freed from its attachment, the parts in the immediate neighborhood were again explored and the real cause of obstruction was then brought to view. A second loop was found situate immediately below the first, and adherent by an area of about the same size, to the posterior aspect of the body of the pubis. This loop was much more highly vascularized than the first, its color being violaceous or maroon. Its connections broke down more easily than those that bound the first loop to the abdominal wall, and there was considerable venous oozing from the surface detached. After cleaning the pelvic cavity, a drainage-tube was passed into the abscess, and the first and lowest silver suture was so arranged as to cut off entirely and securely all communication between that cavity and the peritoneum. The remainder of the wound was closed with a dozen silver sutures, with intermediate superficial ones of silk. The line of incision was covered with a strip of lint saturated with carbolized oil, and the whole abdomen with a thick layer of cotton and bandage. It was found

[1] Read before the New York Surgical Society, May 23, 1882.
[2] History by Dr. Thomas W. Bickerton, Resident Physician.

impossible to determine correctly the precise relationship of these two adherent loops, but as there was a marked difference in the appearance of the two, the deeper one being much more highly congested, it is more than probable—indeed it was regarded as demonstrated—that its lumen was occluded by the loop that lay above it. After operation patient was given brandy, ʒ iv. hypodermically, and returned to bed with hot bottles to the extremities. December 15th, 9 A.M.: Patient passed a fair night. comparatively free from pain, sol.morph.U.S. P., ʒ i., being given every two hours, but complained of feeling very weak. Pulse, 116; respiration, 24; temperature, 101°. Ordered beef-tea and milk-punch every half hour, alternately. 11.30 A.M.: Called and found patient failing—cold extremities, and feeble, rapid pulse. Hot bottles were applied, and was given brandy hypodermically. 2.15 P.M.: Patient died.

Necropsy, twenty-six hours post mortem. Rigor mortis strongly marked. Body emaciated, not to marked extent. Abdomen quite distended, and in median line extending from near the umbilicus to symphisis pubis an incision held together by alternate silver and silk sutures, at the lower part of which a drainage-tube emerged. The wound showed partial primary union to have taken place throughout. *Thoracic cavity.*—Heart healthy. Lungs: right, few adhesions of pleura, emphysematous at apex to slight extent, congested posteriorly; left, markedly adherent to parietes, markedly emphysematous at apex and congested posteriorly. *Abdominal cavity.*—Liver healthy; spleen healthy. Kidneys: right, enlarged, on section pale, cortex quite thin and striæ not marked, capsule stripped off; left, same changes as in right, but not so marked. Bladder dilated, walls thinned, and cavity filled with urine. Intestines: small, marked venous congestion, distended with gas and a small amount of diffluent fæces; eighteen inches from ileo-cæcal valve was found the remains of one adhesion which was broken down at time of operation. It was highly congested and showed that the peritoneum had been denuded from the gut over a space the size of a five-cent piece. About two inches nearer the termination of the ileum was found the remains of the other adhesion released by the operation. It was not congested nor was there any laceration of the peritoneum. There was also discovered one other adhesion still existing between the intestinal coils, but not so as to produce any occlusion. The large intestine was not congested, but was greatly distended with gas from the caput coli as far as the splenic flexure; at this point the omentum was slightly adherent to the gut, but there was no evidence of recent peritonitis. Beyond this point the large intestine was in a collapsed condition. From the pale condition of the gut it was evident that there had been no involvement of it in the obstruction, but that the gas had probably passed into it from the small intestine after the liberation of the latter by the operation. The sharp angle at the splenic knuckle prevented the gas from passing freely onward, though it could be *milked* through—hence the collapse of this portion. Between the body of the pubis and the fundus of the bladder was found the abscess opened in making the abdominal incision, and into which was passed the drainage-tube. It was about the size of a pigeon's egg and contained a small quantity of offensive pus. The connective tissue beyond the abscess presented a healthy appearance.

Remarks.—The sequence of events stand out with sufficient prominence to be easily understood. Aspiration with a faulty needle had permitted the escape of urine into the connective tissue in the neighborhood of the bladder, this had caused abscess, a local peritonitis and adhesion of the nearest loops of intestine, the loop first found had formed a bridge or arcade, under which the deeper loop became engaged, and was probably strangulated by the tense mesenterial band of the first.

In THE MEDICAL RECORD of 1879, a case of intestinal obstruction of eight days' duration was published by Dr. G. W. Hunt, of Cornish Flat, N. H., in which I performed the operation of lumbar colotomy. The case was subacute in character, the obstruction low down, and the issue was successful.

In THE MEDICAL RECORD, May 15, 1880, I reported a case of acute intestinal obstruction of six days' duration that occurred in the practice of the Presbyterian Hospital, laparotomy was done, a portion of the ileum was found strangulated in a subperitoneal hernial sac, the orifice of which was situate close by the internal ring. The patient died.

These cases which came under my immediate supervision, and others of a kindred character, that I have seen in the practice of my friends have impressed me with the conviction that the embarrassment which we feel in the presence of such cases is largely due to our lack of familiarity with the very various pathological conditions that we may have to deal with. The literature of the subject is comprehensive enough, and I have thought that it would repay the labor of an attempt to condense into a small space those points that might enable us to differentiate between the various forms of obstruction and their seat.

Age is an important element in the diagnosis. In early life invaginations are a common cause, fifty per cent. occurring during the first ten years, twenty-five per cent. during the first year. The symptoms are plain enough, and yet they are not infrequently mistaken for dysentery, entero-colitis, and peritonitis, the ileo-cæcal is the most common and its extent will vary of course with the extent to which the entering layer is projected into the receiving layer; the anatomical cause for its frequency will be found in the greater mobility of those portions of the gut in early life. The symptoms appear suddenly with violent colic, vomiting, and evacuations of bloody mucus from diapedesis and rupture of blood-vessels caused by compression of veins of the invaginated mesentery, these discharges occur in no other obstruction save that caused by twisting of the sigmoid flexure. Meteorism may be marked in the invasion and may subside with the advent of the bloody stools referred to. The most important symptom is the presence of a tumor formed by the invaginated intestine, it may be felt through the abdominal walls at varying points along the course of the colon, and its formation and extension is so rapid that in some cases it can be felt in the rectum on the second day. In old age the diagnosis will generally rest between impaction of intestinal contents and cancer. The records contain numerous examples of the former in which habitual accumulation of fæces in the rectum and sigmoid flexure of old people have led to permanent arrest of peristalsis, to paralysis, and hyperextension. Such conditions are usually preceded by coprostasis, which may be due to chronic catarrh, the use of too little fluid, or too much vegetable food. A careful examination by manipulation through the abdominal walls and with the fin-

ger in the rectum will suffice to determine the existence of impaction.

Malignant disease may show itself in the localized annular form, in which the impaction of undigested food may produce prompt occlusion, or it may occur in the form of diffuse cancerous infiltration; these conditions will occur in persons in whom there is evidence of disturbance of general nutrition, emaciation, change in the color of the skin, recurring symptoms of obstruction, attacks of partially interrupted permeability, to which may be added the grave phenomenon of total definitive occlusion, the milder attacks increasing in frequency with the advance of time and yielding less readily to the means used for their relief. Sometimes we may be able to discover a tumor, and it may be difficult to decide whether it be neoplasm or fæces. If it neither changes its shape or position, it is probably the former, but it may be distended and hypertrophied intestine above a constriction. In such cases, if it diminish in size, or disappear when the temporary obstruction has passed through, then it may be possible under ether to discover the permanent cause.

Between the two extremes of life we shall meet with all those various occlusions that have done so much to baffle the best-directed efforts of the diagnostician, or it would probably be more correct to say that whilst the causes we have referred to belong almost exclusively to the extremes, those to which I shall only briefly refer may occur at any period. Internal strangulations of the intestine by peritoneal false ligaments, bands passing from one loop to another, from a loop to its mesentery or the abdominal wall, through buttonholes in false ligaments, in the mesentery or omentum, any of these may be suspected where there is a history of a previous peritonitis. Strangulations by diverticles occur between the ages of twenty and thirty. Strangulation of internal hernia in pouches of the peritoneum are too numerous in their varieties and character to permit of description in an article like this, and we can only refer to cases of knotting and twisting as such that are usually hyperacute in character, correspondingly rapid in the development of symptoms, and most fatal in results.

I will now pass on to the consideration of those symptoms that may enable us to form an opinion as to the seat of obstruction. A previous history of peritonitis, especially such as is limited to the pelvic region in the female, may warrant a suspicion either as to character or location.

Feelings of abdominal discomfort, fixed or recurring pain in the same spot may lead to physical explorations through the abdominal walls, in the neighborhood of the different outlets, or by Simon's method, that may determine the location with some approach to precision. Enemas have been used for the same purpose of determining the capacity of that portion of the intestine that lies below the obstruction. From experiments made on the cadaver, Brinton concluded that if 500 c.ctms. of liquid could be injected, the obstruction could not be lower than the upper end of the rectum; if 1,500 c.ctms., it could not be lower than the upper end of the sigmoid flexure. In a case of occlusion of the ascending colon, four and one-half litres were injected. Cadge did a colotomy where a sound only passed six inches, and only a few ounces of water could be injected, and in which the obstruction was found in the ileum. Great differences are met with as regards the toleration of enemas, and those who have had most experience with them as means of diagnosis, have rejected them as unreliable.

The first symptom that naturally attracts attention is constipation, which is present in the very large majority of cases, but as stated when speaking of invaginations, there may be discharges of blood and mucus; the same may occur in twisting of the sigmoid flexure and in incomplete obstructions; the possibility of copious diarrhœa is not to be denied when the obstruction is high up in the jejunum or duodenum, and has been ascribed to the extension of the peristaltic movements to the portion lying below the occluded point. Brinton attributed such discharges to transudation, but experiments by German observers have proved that they were the result of increased peristalsis. Of course the intestine below the obstruction is emptied of fecal matter in all cases in the beginning of the attack, and save in the exceptions referred to constipation is the rule.

Pain often follows the occurrence of obstruction with a rapidity and suddenness which scarcely admits of the appreciation of an interval of time, its amount and duration being commensurate with the degree of local injury that is associated with the obstructed state; it is intense in intussusception and the impaction of gall-stones, less so in constrictions by bands, still less in the obstruction of stricture, and almost absent in the cases of impaction of fæces in the large intestine; there is a steady, constant, and continuous pain, aggravated by paroxysms that appear to be coincident with the peristalsis of the bowel; often they begin as light, colicky pains, rapidly increasing, sometimes spreading over the whole abdomen, sometimes circumscribed, and limited to the region of the umbilicus.

Vomiting will usually be relative with three conditions, and proportionate to them, the nearness of the obstruction to the stomach, its tightness, and the persistence with which food and medicine have been administered. If the obstruction is situate in the upper portion of the small intestine, below the orifice of the common duct, the ejecta will be colored with bile; when it is situate in the ileum they begin to assume a fecal character; when in the colon stercoraceous vomiting occurs, the fæces are finely disseminated through the fluid by the movements imparted to it by the peristalsis. Of course it is understood that the contents of the colon can only pass into the ileum when the ileo-cæcal valve has become insufficient by distention and simultaneous paralysis of the cæcal sphincter. Stercoraceous vomiting occasionally occurs in cases of diffuse peritonitis without demonstrable obstruction, but this condition will be differentiated by the presence of other symptoms of serous inflammation, the tenderness on pressure, increasing distention, projection of borders of ribs and hypochondria, disappearance of region of dulness over the liver, elevation of temperature, intensified collapse, and increased frequency of pulse.

The amount of urine passed has been regarded by some observers as a guide to the location of the obstruction. It has been supposed that when it occurred high up in the intestinal canal, there would be a diminution in the quantity secreted corresponding to the small absorbing surface above the obstruction, this may undoubtedly exercise some influence, but it is more probable that the anuria arises from the withdrawal of water from the system by the vomiting, and by the diminished blood tension in the vascular system of the kidney, resulting from shock. At all events, the observation of acute cases

has shown the condition to be a fallaceous guide in determining location, it is useful for such a purpose only in the chronic incomplete occlusions.

By making frequent examinations in the beginning of the attack we may often learn much that may throw important light on both the character and situation of the stenosis. In chronic obstructions there may be marked meteorism, and the writhing convolutions can be seen through the abdominal walls, while in acute cases the meteoristic abdomen is distended smoothly and equally, and no movements are visible. In occlusions occupying the upper portion of the small intestine the meteorism is not marked, and is limited to the epigastrium; in those occurring in the lower part of the small intestine, the swelling is noteworthy, and limited mainly to the meso- and hypo-gastrium, obstructions in the descending colon are marked by meteorismus confined to the region of the large gut. These indications can only be found early, the rapidly increasing distention of either small or large intestine, soon obliterates all evidences of the condition we are considering.

The few remarks I have made on the subject of diagnosis are by no means to be regarded as exhaustive, rather as suggestive, and simply to express my conviction, that a correct or approximately correct appreciation of the character and location of an obstruction is possible in many cases, and ought to precede any treatment that we may consider appropriate, and likely to be successful. The subject is a very comprehensive one, and those who would wish to study it more in detail, I refer to the sources from which I have obtained much that is contained in this communication.[1]

If we approach a case of intestinal obstruction, as one that is necessarily fatal, it will very likely prove so, but if we recognize the established fact that there is scarcely any form from which it is not possible for a patient to recover, we shall very likely save many cases that would otherwise die. Even in the most fatal class of cases in which an autopsy has revealed a band as the cause, the history of the patient has often shown that he has recovered from previous attacks precisely similar to the last fatal one, the cases that most frequently do well are the protracted ones that last sometimes for weeks, but recoveries are recorded in acute cases in which the patients appeared to be at the last gasp.

In cases of "ileus paralyticus," or obstruction from impaction of fæces, the cases that have been preceded by gradually increasing constipation, in which the colics have not been severe, in which there has been little or no vomiting, it may be proper to administer a dose of calomel, to be followed by castor oil or a saline laxative, and to resort to the use of enemas. In all other cases, no matter what the anatomical character of the obstruction may be, if the symptoms are acute, we must scrupulously avoid the use of cathartics of any kind whatever, they can only do harm by increasing the distention of the gut above the obstruction, by aggravating the peristalsis and the consequent pain, and the vomiting and its consequent, the collapse. Opium is the only agent that can help us under such circumstances, it is best given in the crude or solid form, by the mouth or rectum, and it must be given liberally in doses sufficient to put a stop to pain. If rejected by the stomach it may be used hypodermically, and there is no advantage in combining it with any other narcotic. Pfeufer, referred to by Leichtenstern as an authority, is a warm advocate for the exclusive use of opium in all forms of obstruction, he does not permit the use of even an enema until forty-eight hours after the subsidence of pain, and sensitiveness to pressure.

There can be no doubt, from the histories of recorded cases, that large enemas sometimes give prompt relief, but they must be used as recommended by Hegar, through the anus by a funnel apparatus—glass funnel, rubber tube, and rectal sound; the patient must be inverted, or in the knee-elbow or knee and head position; they must be given warm to the amount of several quarts, and they must be administered when the patient is narcotized with opium or ether, or both combined. The enemas must be repeated at least three times a day.

Massage or abdominal taxis has been advised by Jonathan Hutchinson, and by Sagar; the former employing it under anæsthesia, the latter in the warm bath.

I have stated that the cases of obstruction that have a tendency to get well are the subacute or protracted ones, in which all the symptoms are mild in character. In some of these, however, the obstruction which is generally found in the large intestine, and which may be stricture or tumor, refuses to yield, and it may be necessary to open the intestine above the stricture. The proper operation in such cases is colotomy, either right or left, depending on the situation of the obstruction. Some surgeons prefer in these cases to open the cæcum through the anterior abdominal wall, laparotyphlotomy or laparocolotomy, Littrè's operation.

There still remain for consideration those hyperacute cases that so often foil the best-directed efforts of the physician. Under this head must be classed the strangulations by false ligaments, bands, diverticles, twists, slits in the omentum, and internal hernias. The small intestine is the part most frequently involved, though twisting of the sigmoid flexure may be associated with grave symptoms. These strangulations all commence with severe agonizing pain, collapse, vomiting, and anuria, which rapidly reach a considerable height. They are to be met promptly with a liberal use of opium, anæsthetics, and large enemata, and if the symptoms are of such a violent character as to indicate early dissolution, the propriety of operative interference may be seriously entertained. The recognized mortality of these cases would seem to justify such a procedure, though in the absence of very definite knowledge of the anatomical character and seat, it may, by many, be regarded as better to trust to the chance of spontaneous cure. I feel sure that uncertainty of diagnosis often deters the surgeon from operating, the fear that the section may expose conditions not previously ascertained; and yet I think that in many cases a careful analysis of the symptoms ought to enable us to express a tolerably exact opinion.

If the symptoms indicate that the obstruction is high up in the small intestine, laparotomy is the best selection; if they are such as to point to the existence of constriction in the lower end of the ileum, we may do laparotomy, or Nélaton's operation—laparo-ileotomy.

Cases of intussusception rarely call for abdominal section; there do occur occasionally cases of acute invagination, with early and complete occlusion, in which it may be required, but they are very rare. According to Brinton, thirty or forty per cent. of

[1] Leichtenstern: Ziemssen Cyclopædia, vol. vii.; Hutchinson, Jonathan: British Medical Journal, August 31, 1878; Whitall, Samuel: New York Medical Journal, 1878; Brinton, William: Croonian Lectures, London Lancet, July, 1859.

such cases get well by processes resulting in separation of the intussuscepted portion. An operation done late might be dangerous; we might set free a sphacelated gut that was comparatively harmless, ensheathed within the receiving portion of the gut below, and isolated from the peritoneum by adhesions.

HALLUX VALGUS, WITH DISPLACEMENT OF THE SMALLER TOES.

By A. C. POST, M.D.,
NEW YORK.

In March, 1882, I was called to see I. D. S——, a gentleman who had a deformity of the left foot, with the following history: Age of patient, forty; his foot was in a normal condition until he was six or seven years of age, when he received a punctured wound from a pitchfork, on the inner side of the left foot, near the ankle. This was followed by severe inflammation, which continued three months, and left the foot in a flattened and valgous condition. The motion of the ankle was impaired, but not lost. When he was nineteen years old, he injured himself by jumping from a wood-pile, after exposure to cold.

This injury and exposure were followed by osteoperiostitis, resulting in necrosis of the tibia. He had also synovitis of the knee, leading to a very firm false anchylosis in a straight position, continuing to the present time.

When he was twenty years of age, I was in the part of the country where he resided, and was called to see him. I made an incision over the tibia, and removed a sequestrum. Soon after he began to go about, after the operation, his toes began to be displaced, and the deformity gradually increased until he came under my care in March last. The pressure of the great toe upon the other toes crowded them out of their normal position, and occasioned great pain and disability in walking. The fourth toe, especially, suffered so much from the pressure that he applied to a surgeon in 1867, and had it amputated.

The following was the condition of the anterior part of the foot when he came under my care: The great toe was subluxated at the articulation with its metatarsal bone, and was thrown obliquely outward and forward, resting on the dorsal surface of the second and third toes, which were subluxated downward and outward at the articulations with their metatarsal bones. The little toe was flexed at a right angle, at the articulation of its first and second phalanges, and its distal extremity was directed vertically downward.

On March 14 I performed the following operation: I made a longitudinal incision over the anterior part of the dorsal surface of the metatarsal bone of the great toe, extending it over the posterior part of the first phalanx. The incision over the metatarsal bone divided the skin, the expansion of the extensor tendon, and the periosteum, exposing the bone denuded of all its coverings. I opened the

joint, and caused the extremity of the metatarsal bone to protrude through the wound, and passed beneath it a chain saw, by means of which I readily separated the articular extremity from the body of the bone. I then cut down in like manner upon the dorsal surface of the distal extremity of the second and third toes, causing the bones to protrude, and excising their articular extremities with Liston's bone forceps. After this, I excised, in like manner, the distal extremity of the first phalanx of the little toe. The several toes were then brought, as nearly as possible, into their normal position, and maintained in it by a stiffened felt splint with digital divisions, applied to the plantar surface of the foot, strengthened with bands of hoop iron on the distal surface, and supported by strips of adhesive plaster and a roller bandage. Before applying the splint, I washed the wounds thoroughly with carbolic acid, 1 to 40.

March 15th.—The patient has suffered so much pain about the wounds, that he could not sleep without an anodyne.

March 17th.—The lips of the wounds are inflamed, and there is some suppuration.

March 20th.—The inflammation is subsiding. I

took off the plantar splint, and supported the great toe by a splint of hoop-iron, lined with lint, and secured to the inner side of the foot with strips of adhesive plaster. A compress of lint was then applied between the great toe and the second, and a strip of adhesive plaster was passed around the two toes, securing the second toe in position by the support of the great toe. The third toe was secured in like manner to the first and second. The little toe was supported by a strip of whalebone, wrapped in lint, applied to the dorsal surface, and secured by strips of adhesive plaster.

The parts were dressed in the same manner, on March 23d, 27th, and 30th, and on April 3d and 10th, after which I did not see the patient again until May 12th, when he brought me the cast exhibiting the improved position of the toes. The patient is able now to wear a laced boot, the anterior extremity of which is shaped so like that of the boots generally worn as not to attract attention. He walks without much discomfort, and there is considerable motion at the newly formed articulations. There is still some tenderness on pressure, but it is gradually diminishing.

ON THE USE OF SILKWORM-GUT SUTURES IN GYNECOLOGICAL SURGERY.

By G. H. BALLERAY, M.D.,

SURGEON TO THE WOMAN'S HOSPITAL, NEWARK, N. J.

The value of silkworm-gut as a substitute for silk or silver-wire sutures, in all gynecological operations, is not sufficiently appreciated by the profession in this country, and the object of this communication is to draw attention to the merits of this article and invite a trial of it. I have, during the past year, used silkworm-gut in all my operations for laceration of the cervix uteri and perineum, and for closing the abdominal wound after ovariotomy.

The advantage of silkworm-gut sutures, over those of silver wire, are, that they are more easily introduced, and much more easily removed. In operations for laceration of the cervix uteri, if the sutures are only drawn to the requisite degree of tightness, they may remain undisturbed for two weeks, without causing any ulceration. This, in my opinion, is a great advantage, for I believe that failure after hystero-trachelorrhaphy is very frequently due to too early removal of the stitches. The ease with which the sutures are removed is also a great advantage, as the line of union is not unfrequently strained, if not actually torn open, by bungling attempts to remove silver-wire sutures—even in the hands of those who, in introducing the sutures, display considerable manual dexterity. For operations on the perineum, and for closing the abdominal wound after ovariotomy, what is known by dealers in "fishing tackle" as "salmon-gut" should be used; while for closing a lacerated cervix, the intermediate size is quite strong enough. In no case of operation for lacerated cervix should the sutures be removed before the tenth day; and it is much better to leave them in until the twelfth or fourteenth day. Silkworm-gut should be kept either in water or some antiseptic solution for some hours before it is required for use, for if not thoroughly moistened it is stiff, and difficult to tie in a tight knot.

Dr. George Granville Bantock (Surgeon to the Samaritan Hospital for Women, London), uses silkworm-gut sutures in all his operations (four-fifths of which are ovariotomies), and it was through his teaching that I became a convert to their use; but I need hardly say that his excellent results are in nowise due to the kind of suture that he employs, but to his neatness and dexterity as an operator, and his consummate skill in the treatment of his cases.

GELSEMIUM IN RHUS POISONING.

By BENJAMIN EDSON, M.D.,

BROOKLYN, N. Y.

At this season of the year poisoning from ivy, oak, and mercury is far from infrequent. The affliction may not be particularly dangerous, but it is often painful, tedious, and annoying to both patient and physician. The usual treatment by the application of lead washes, alkalies, and various mercurial solutions, so far as I have observed, has rarely exerted any marked effect upon such cases, and has often been destitute of the merit of being even palliative. The chief satisfaction has usually been that something was being done, and presumably the best that could be done under the circumstances. Bromine in olive oil is claimed to give prompt relief, but of its use I have had no practical knowledge.

In spite of the various modes of treatment, the summary given by Duhring, "Disease of the Skin," p. 326, represents about the general experience: "The process may continue from one to six weeks according to the severity of the attack and other circumstances, as, for example, treatment. Under proper treatment the majority of cases recover in the course of a fortnight."

Last summer it was my unusual fortune to see a large number of cases, and their treatment proved so satisfactory that I feel justified in calling attention to it. The first case was a very severe one—that of a lad fourteen years of age. I saw him on the third day after he had come in contact with the poisonous plant in New Jersey. I found his hands, arms, and legs swollen to nearly double the ordinary size, skin over a portion of the affected part tense and hot, covered with nodules and vesicles of various sizes and stages, some of them burst open and discharging an abundance of irritating fluid. The penis and both cheeks were also involved to some extent. The suffering was almost unendurable. Nothing that had been applied had given any relief. Having used gelsemium for some years with much satisfaction in pruritic troubles, it occurred to me that it might at least alleviate the pain in the case. I therefore extemporized a wash in about the following proportions:

℞.	Acid. carbolic	ʒ ss.
	Ext. gelsem. fluidi.....	ʒ ij.
	Glycerinæ	℥ ss.
	Aquæ.....ad.	ʒ iv.

M.

With this, cloths were kept moistened and applied to the parts affected. Internally, the fluid extract gelsem., ♏ ij. every three hours.

The pain speedily subsided. The burning, itching, corroding sensation ceased. Within thirty-six hours the disease appeared to be effectually *killed*. The progress to complete recovery was direct and rapid.

Subsequent cases were treated in essentially the

same manner, with the exception of two, in which carbolic acid was not used, and these yielded no less promptly than the others.

From the two series of cases thus treated I have great confidence that gelsemium, topically and internally, will afford prompt and permanent relief in rhus poisoning.

83 St. Mark's Avenue, Brooklyn.

Progress of Medical Science.

A Successful Case of Sponge-Grafting.—Dr. Norman Poeritt reports a case of sponge-grafting, conducted according to the method proposed by Dr. Hamilton, in the *Edinburgh Medical Journal*, for May, 1882. Those readers who are unacquainted with Dr. Hamilton's process of sponge-grafting are referred to his original paper in the same journal for December, 1881. The patient was a boy fourteen years of age. He had fallen against a revolving drum, and his right cheek presented an oval charred cavity four inches long and two inches in the greatest breadth. The cavity had the appearance of a burn, the result of the severe friction to which the surface had been exposed. A piece of sponge, prepared according to Dr. Hamilton's directions, was so placed as to exactly fill the cavity, without rising above its margin. Protective silk was laid over the sponge and the whole secured with plaster. Boracic lint and wadding and a bandage completed the dressing. On the fourth day after the dressing was applied, a small granulation was found protruding through the upper portion of the sponge. Five days later the sponge had been completely concealed by the granulations, but could be detected by displacing the latter with a forceps. After two weeks the whole of the sponge had disappeared, with the exception of a few small particles. Its place was occupied by healthy granulations, at the border of which cicatrization was taking place. After another period of four days the wound was only three-fourths of an inch long and one-fourth of an inch broad, and was rapidly cicatrizing.

The Relations between Asthma and Mucous Polypi of the Nasal Passages.—The *Archives Générales de Médecine* for May, 1882, contains the termination of a serial article by Dr. Joal, of Mont Doré, upon the above subject. The conclusions réached by that author may be summarized as follows: 1. Nasal mucous polypi sometimes occasion asthmatic symptoms. 2. This symptomatic asthma is principally observed in gouty subjects. 3. The disease is usually produced by a reflex action secondary to an irritation of the nasal mucous membrane. 4. The reflex excitation may, however, have its point of departure in the sensitive filaments of the pneumogastric which supply the pharyngeal or bronchial mucous membrane. 5. Asthma may be developed as the result of catarrhal and emphysematous lesions referrable to nasal polypi. 6. The asthmatic paroxysms are relieved or completely disappear after the removal of the polypi. 7. The nervous symptoms provoked by nasal polypi consist, sometimes, in spasmodic paroxysms of sneezing.

External Follicular Vulvitis.—The following is a *résumé* of the conclusions arrived at by Drs. Gonguenheim and Soyer in the course of an article with the above title, published in the *Annales de Dermatologie et de Syphilographie* for April, 1882. The varieties of follicular vulvitis are: 1, simple acute follicular inflammation; 2, acne due to different causes; 3, syphilitic acne; 4, syphilitic follicular inflammation. Simple follicular vulvitis is rare. It terminates most frequently in furuncalar inflammation. The acne due to causes other than syphilis does not differ, in any way, from the same affection when developed in other regions. Syphilitic acne does not differ from the preceding variety. It may not appear in a pustular form, or, having become pustular, may ulcerate. Several ulcerated follicles may unite and simulate a simple chancre. The syphilitic follicular inflammation is an interesting but often misinterpreted form of simple chancre, which it usually accompanies, and to which it is most frequently secondary. This variety of chancre develops very slowly; it may become abortive, or may ulcerate and assume the appearance of a true chancre. The pus from syphilitic folliculitis is quite as virulent as that of a simple chancre. The differential diagnosis of these various affections is, generally, easy. Simple acute folliculitis is distinguished by the rapidity and severity of its course. The nature of the various kinds of acne is determined by the concomitant signs of the diathesis or disease producing them. Syphilitic follicular inflammation is distinguished from simple acute folliculitis by its limited extent, by its tendency to rapid ulceration, and to the invasion of adjoining follicles, and by the presence of a chancre in its neighborhood. In doubtful cases inoculation settles the question. The morbid anatomy of these varieties of follicular inflammation is not different from that of folliculitis in other localities. Topical treatment is alone necessary for simple and syphilitic follicular vulvitis. Internal and external treatment must be combined in cases of chronic follicular inflammation of, or folliculitis dependent upon a diathesis.

Sensory Epilepsy.—In the *New York Medical Journal and Obstetrical Review* for June, 1882, Dr. Allan McLane Hamilton presents a paper on cortical sensory discharging lesions (sensory epilepsy), or that form of epilepsy in which the sensory element preponderates, whether as an aura preceding a motor discharge, or occurring as a part of a paroxysm in which there is little or no succeeding motorial disturbance, but simply a discharge consisting of a preliminary alteration of special sensibility, and an immediate subsequent stage of unconsciousness. In the majority of these cases there is, he remarks, the simplest form of subjective consciousness of sensory impressions, most of the attacks consisting of the primary stages suggested by Jackson, such as a sudden stench in the nostrils, or colored vision; but in two or three instances there has been much more than this, and the phenomena have been quite remarkable. In some cases the occurrence of a transient contraction of the fingers of one hand lent additional interest to the history, especially in regard to localization. In one case the patient's sensory condition was not the dreamy state referred to by Jackson, but there was always an hallucination of taste, the patient declaring that he had tasted copper or some other nauseous substance; and in other cases there were equally striking proofs of the primary involvement of the cortical centers. The occasional occurrence of hallucinations as a part of the epileptic attack has been mentioned by various authors. Brierre de Boismont, Esquirol, Delasiauve, Maison-

neuve, Billod, Sommers, Bergmann, Guislain, and Tigges, as well as many other writers, have furnished cases which began with sensory auræ or hallucinations, but none of them, says Dr. Hamilton, have made a distinct classification of sensory and motorial epilepsy, and but little mention is made of the disease where the paroxysms consist solely of sensory phenomena, the disturbance of motility being absent. He has not, so far, met with cases in which the individual was influenced by his hallucinations to express them by special motor acts before the attack, except in an unimportant way. On two occasions he has been present at the beginning of a sensory attack. In one instance the patient complained afterward that he smelt a horrible stench. Immediately before losing consciousness he carried his hand up to his nose, and immediately afterward became oblivious to everything about him. A similar action was performed by a patient who forcibly placed both hands over his eyes, as it afterward transpired, to keep out a bright light that blinded him. In the light of all that has been done in the localization of cerebral disease, Dr. Hamilton thinks that we should discover, if possible, the part played by the cortical sensory centers in the genesis of such epilepsies. So far, little has been brought forward to connect lesions of the sensory centers with special symptoms. In our pathological discussion of sensory epilepsy, the distinction should be made between lesions of the thalamus opticus and those of the cortical sensory zones, for in the one instance the sensory disturbance may be called the essential, while in the other there may be said to be an affection of special subjective consciousness. If an impression upon the organ of sense is sufficiently intense to impress the infra-cortical central sensory apparatus (thalamus opticus) centripetally, it does not follow that there need be any implicated alteration of function in the cortical sensory regions. A lesion of the posterior part of the thalamus opticus, for example, may result in blindness—a *mechanical* blindness, if such an expression can be used, though there are exceptional cases reported by Brown-Séquard where even this is not the case—but it will not produce *word*-blindness, a purely psychical defect. There must be some altered cortical function to account for the unmistakable mental operations which permit the individual to recognize the altered sense-states and enter into the involuntary formulation of hallucinations which are afterward remembered. The author therefore does not believe that the disease of the thalamus opticus *alone* plays any part in the origination of hallucinations. He thinks we may recognize a form of epilepsy of sensorial character, the motorial features being either absent or insignificant; that such sensory manifestations arise from an unstable condition of the sensory cortical centers; that a light grade of sensory disturbance may indicate simply a suspension of inhibition through an exhausted state of the perception centers which are infra-cortical, or a suspension of the influence of the superior cortical centers, in which case the process is more complex, and the result may be the formation of hallucinations.

Terrier on a First Series of Twenty-five Ovariotomies.—M. Terrier has summarized a number of conclusions from his first series of cases. Among them the following are the most noteworthy: Ovariotomy is usually performed between the twentieth and fortieth years of life, though it may be practised up to the sixtieth. Ovarian cysts produce little change in the menstrual function, and do not necessarily occasion sterility, partly because they may be unilateral, partly from the slowness of their growth. The evolution of these tumors is often very rapid. In all cases an early operation is indicated. Sometimes the morbid phenomena which attend their development may be trivial, except so far as the bulk of the growth is concerned, at which times severe pain and peritonitis may supervene, and in such cases adhesions are pretty uniformly produced. Ascites is an important symptom, especially if well marked. It indicates the presence of polycystic vegetating growths. Slight ascites has little diagnostic or prognostic significance. Œdema of the limbs and of the abdominal walls has a constant relation with the volume and seat of the growth. Pulmonary complications and phlegmasia alba dolens are serious, but fortunately rare concomitants. Puncture for purposes of evacuation or exploration is free from danger if accomplished with care. It ameliorates the symptoms and enables the surgeon to be more precise in diagnosis and prognosis. The results of operations have varied little. Full Listerism has been employed, or other less exclusive methods. Personal experience does not enable M. Terrier to say whether or not it is better to fasten the pedicle within or without the abdominal walls. Multilocular cysts are the most frequent. The percentage of mortality was twelve, *i.e.*, three out of twenty-five. The cause was uniformly acute suppurative or non-suppurative peritonitis. Among the sequences of the operation, central hernia through the abdominal cicatrix is mentioned, and it is inferred that serious trouble may result therefrom.—*Revue de Chir.*, May, 1882.

Tuberculous Synovitis of Tendinous Sheaths.—Although tuberculosis has been found in nearly every part of the human body, it does not seem that there has been any distinct proof offered of its presence in the sheaths of tendons. M. Janin, in the service of M. Trélat, at the Hôpital Necker, now publishes a case which he thinks has the histological evidence that is necessary to establish the fact satisfactorily. A female, nineteen years of age, of strumous habit, and constant tendency to colds, entered the hospital in December last. She was found to have inflammation of the flexor tendon sheaths of the right middle finger, the tumor, eight to nine centimetres long, extending under the palmar arch. It was removed in its totality by M. Trélat. A microscopic examination by M. Latteaux showed that it contained nodules, cheesy foci, and giant cells, which were thought to substantiate the diagnosis of tuberculosis, since the author holds that these histological findings are proof conclusive of the constitutional disease.—*Prog. Médicale*, June 19, 1882.

Source of the Bothriocephalus Latus.—Though it has long been known that tapeworms gain access to the body through the medium of measly animals, hogs furnishing the tænia solium, horned cattle the tænia mediocanellata, the source of the bothriocephalus latus has been unknown, though, according to Knock, it develops in the water. This author holds that the parasite, unlike the other tapeworms, has no intermediate bearer, though it seems now clear that the cysticercus has been found in certain fish, and it was even suspected that the pike and lota were the fish usually selected. Since the cysticerci cannot with certainty be differentiated from other larval forms, they have been fed to cats and dogs, developing the mature bothriocephalus, which

in size and other characteristics could not be distinguished from the human form. In pike the parasites are said to be *usually* found, the middle-sized fish having from forty to fifty cysts. Of more than sixty that were examined, but one had muscles that were not so infested.—*St. Petersburger Med. Woch.*, May 16, 1882.

HENRIET ON SUB-PERIOSTEAL AMPUTATIONS.—Apropos of a communication made some time ago to the Société de Chirurgie, M. Henriet has undertaken a review of the subject (*Tribune Médicale*, April 30, 1882). Sub-periosteal amputation consists, as is well known to surgeons, in preserving a considerable portion of the periosteum beyond the point where the bone is severed by the amputating saw. This redundant membrane constitutes a cuff (manchette) as it were. In M. Méaise's patients, one in particular, on whom an autopsy was subsequently made, proved how practical the measure may be, for it was found that the periosteum had, in covering over the cut end of the bone united firmly to it, obliterating the medullary cavity, and of course presumably preventing the ordinary hemorrhage from the bone. And yet the operation has not met with favor, because either there has been a lack of periosteum, or it has been found so lacerated after denuding the bone that its efficacy was thought problematical. The periosteum of the adult, which has completed its task of bone-formation, lacks the qualities suited for the purpose and is thin, as compared with the same membrane in its active period of development or about an inflamed joint. M. Ollier, however, believes that it is an operation admitting of generalization, the dangers being on the side of an excess of bone-production. Thus, in young children, he has found the periosteum produce osteophytes to the damage of the stump. Still he admits that often he does not practise the operation.

If one needs periosteum, says M. Henriet, in considering the pros and cons of the measure, one does not need too much. The operator should strip the bone carefully, but be mindful at the same time that the absolute integrity of the periosteal cuff is not indispensable, having in fact sometimes the drawbacks that have been mentioned.

From an American standpoint it still appears doubtful if the precise field for the operation has been well defined. Evidently youth of bone and some sort of antecedent inflammatory action in adjacent parts renders the new production of bone more probable.

NEW APPARATUS FOR TREATING CARIES OF THE SPINE.—Dr. E. Noble Smith has described a new brace and support for treating Pott's disease. The practice of mechanical separation of the carious surfaces he maintains is contrary to the natural processes of cure, which is effected by the coalescence of these surfaces. Caries of the spine should be treated as a local disease, by affording support to and fixation of the spine. This can best be accomplished by spinal supports in the form of back splints combined with recumbency (supine or prone) or by the plaster-of-Paris, felt, or some other kind of jacket without such recumbency. He is opposed to the plaster jacket because thoracic respiration is impeded, and because the suspension required to allow of its application, may prove dangerous, while, too, the position which it produces when first applied is not retained. The treatment he advocates is that introduced by Mr. Chaucer, and called "the skeleton adaptable metal splint." It consists of two light steel bars passing on either side of the spine from a pelvic belt upward to about the level of the second or third dorsal vertebra, where it joins a pad connected to the shoulders by means of straps. The bars are bent to conform with the deformity above, but not below the projecting portion of the spine. Results claimed for this bandage are, fixation of the spine, freedom in thoracic respiration, ease of adjustment, and readjustment if necessary, and daily correction of the support. The author insists upon the importance of recumbency (preferably in the prone position) so long as the disease is running an active course.—*British Medical Journal*, May 13, 1882.

CONTRIBUTIONS TO THE DIAGNOSIS OF ALBUMINURIA.—We are gradually coming to realize the diagnostic and prognostic importance of albumen in the urine, and are being put on our guard against conditions of the urine which simulate albuminuria. Recently, Mr. Carter has offered evidence which appears to have clinical value. Thus, in his paper read before the Cambridge Medical Society on April 14th last (*Lancet*, May 13, 1882), he instanced other substances, such as globulin, ptyalin, pepsin, trypsin, which occur in the urine and may be mistaken for albumen. Statistics show, he claims, that in about one-half the cases of albuminuria, the cause is other than usual. Sometimes it is due to a disorder of the nervous system from prolonged anxiety, or it may be connected in some way with a disturbance of the sexual functions, and this chiefly in males. Sometimes the digestive tract may be out of order, and then the name "food albuminuria" is applicable. In other instances, again, the blood may be at fault, through some change that has taken place in the liquid itself, or it was caused by retardation of flow through some mechanical impediment.

In pregnant women both of these last-named conditions are maintained, for the gravid uterus not only is an obstacle that retards the ascending blood current, but the quality of the fluid blood is altered. In remarks made at the same meeting by Mr. Bradbury, attention was called to the importance of determining the presence or absence of high arterial tension.

Albuminuria coincident with high arterial tension was held to indicate, as a rule, commencing Bright's Disease.

SANITARY CONDITIONS IN RELATION TO THE TREATMENT OF WOUNDS.—Dr. Cabell, at the last meeting of the American Surgical Association, submitted the following propositions:

First.—Statistics show lessened mortality of late years in certain capital operations, especially those involving abdominal section. This is due in part to improved methods, but very largely to strict antiseptic precautions. The mortality in amputations and joint operations has not diminished in equal ratio.

Second.—The continued high rate of mortality from amputations in cities stands in contrast to the decreased general mortality and shows that the sanitary improvement of hospitals is behind-hand.

Third.—The question is asked: Is twenty-two per cent. of mortality for all amputations above the wrist and ankle the best that can be expected? The various influences which oppose the repair of wounds must be studied for an answer.

Fourth.—The prime factor in the repair of wounds is healthy blood, and this should be considered.

Fifth.—Results depend upon constitutional pecu-

liarities, and upon hygienic surroundings, before, during, and after operation. These must also be considered.

Sixth.—Shock, a most common cause of death after primary amputations, owes its malignant potency to the fact that the system has not fully recovered from the previous injury. The desideratum is to prolong the primary or apyretic period. This may be done by Dr. Stephen Smith's method of carbolizing the wounds.

Seventh.—Septic complications have heretofore been the most common cause of mortality.

Eighth.—Much may be done to prevent sepsis by careful attention to all details.

Ninth.—Large hospitals, even those on the block system and of several stories, are not *necessarily* subject to septic diseases, and the mortality here *may* be kept as low as in cottage hospitals or rural districts.

Tenth.—After observing every other sanitary precaution there is good reason to believe that an additional protection of great value may be derived from antiseptic precautions practised in conformity with the Listerian principle.

Eleventh. — "Listerism," practised *de rigueur*, while not so essential in cases of amputation, has achieved results in operations upon joints and in "abscesses from congestion" which have not been paralleled by any other system of treatment.

Twelfth.—The preponderance of evidence is in favor of its utility in ovariotomy and abdominal sections generally.

Ollier on Periosteal Excision of the Wrist.—At a recent meeting of the Academie des Sciences, M. Ollier, of Lyons, stated that, thanks to the combined advantages of Lister's and the sub-periosteal methods, preservation of the hand may now be safely secured in caries of the wrist through ablation of the carpal bones and resection of the radio-carpal joint. Notwithstanding the numerous bones in the carpus, its many articulations, and the limited surfaces of the bones covered by periosteum, the surgeon may still preserve a periosteo-capsular sheath, that will be converted into a new fibrous tissue, which, in the event of the new bone-formation failing, will assure union between the bone of the metacarpus and those of the forearm, and prevent the ordinary results of this operation, viz., flaccidity of articulation and displacement or rigidity of tendons, which have been the main obstacles in re-establishing the functions of the hands and fingers.—*Courrier Médical*, April 29, 1882.

The Antiseptic Treatment of Wounds.—Dr. W. T. Briggs submitted the following conclusions regarding this subject at the American Surgical Association:

First.—The germ theory of wound infection is not established.

Second.—The antiseptic treatment of wounds after operations and injuries is not limited to Listerism or any other special method, but is based upon broad general principles.

Third.—Antiseptic surgery embraces every condition or agent that tends to prevent putrefactive changes in wounds, or to remove or neutralize the evil effects of such changes when they have occurred.

Fourth.—All wounds are healed by reparative inflammation.

Fifth.—All wound accidents are the result, either directly or indirectly, of destructive inflammation.

Sixth.—The antiseptic treatment of wounds, properly considered, consists, first, of such means as will restrain inflammatory action within reparative bounds; and second, of such means as will subdue excessive action, and remove or neutralize the effects of destructive inflammation.

Carbolic Acid in the Abortive Treatment of the Eruption in Small-pox.—New and plausible methods or facts sustaining new methods are always sought for eagerly by the profession, though they usually accept them with a more than usual degree of caution. Now Mr. M. D. Makuna comes forward with a paper which he has read before the Medical and Chirurgical Society of London, in which after enumerating the various ectrotic plans that have been suggested from time to time, he recommends that one first introduced by Dr. Eades, of Norwich, in 1878, and subsequently employed by Sir Joseph Fayrer. It consists in cauterizing the vesicles with carbolic acid. Mr. Makuna finds that eruptions on the face, under the carbolic application, reach the end of the pustular stage in four or five days, while similar eruptions on the body which naturally are far less severe, without the carbolic application, do not mature until many days later.—*Lancet*, May 13, 1882.

Foreign Bodies in the Air-Passages.—Dr. Weist, at the recent meeting of the American Surgical Association, read a paper on the above subject. The following conclusions were submitted by him:

First.—When a foreign body is lodged either in the larynx, trachea, or bronchia, the use of emetics, errhines, or similar means, should not be employed, as they increase the sufferings of the patient, and do not improve his chances of recovery.

Second.—Inversion of the body and succussion are dangerous, and should not be practised unless the windpipe has been previously opened.

Third.—The presence simply of a foreign body in the larynx, trachea, or bronchia, does not make bronchotomy necessary.

Fourth.—While a foreign body causes no dangerous symptoms, bronchotomy should not be performed.

Fifth.—While a foreign body remains fixed in the trachea or bronchia, as a general rule, bronchotomy should not be practised.

Sixth.—When symptoms of suffocation are present, or occur at frequent intervals, bronchotomy should be resorted to without delay.

Seventh.—When the foreign body is lodged in the larynx, there being no paroxysms or strangulation, but an increasing difficulty of respiration, from œdema or inflammation, bronchotomy is demanded.

Eighth.—When the body is movable in the trachea, and excites frequent attacks of strangulation, bronchotomy should be performed.

Innervation of the Rectum.—Irritation of the nervi erigentes causes, according to L. Fellner (*Centralbl. f. Med. Wissensch.*, No. 22, 1882), a contraction of the longitudinal fibres, while it does not affect the circular fibres. These are supplied by fibres from the posterior mesenteric ganglion. The irritation of the long muscle fibres depends not upon the condition of the rectum and its contents, but upon peculiarities of the blood in its vessels.

The Seat of the Muscle-Sense appears to be, from a case cited by Westphal (*Charité Annalen*), in the lower part of the large pyramidal cells of the cortex.

THE MEDICAL RECORD:

THE DECADENCE OF THE AMERICAN FAMILY.

We do not like to be doleful, but it is impossible to ignore some of the facts that have been presented within the last year or two by Dr. Goodell, Dr. Nathan Allen, and others. These facts relate to an alleged change in the physical organization of our men and women, and to the decadence of family life among Americans. Dr. Allen, who has been studying this subject for many years, presents the case very directly in an article entitled "The New England Family" *(The New Englander)*. It is asserted that the objects of the institution of the family are three: the propagation of children, the preservation of chastity, mutual help and company. In each of these respects the American family, especially the New England family, shows a marked and progressive deterioration, since one hundred years ago.

As regards the propagation of children, it is shown that the average native New England family is very much less productive than formerly. This, we are told, is due not alone to the induction of abortions and the prevention of conception, as was at one time asserted, but to a change in the physical organization of the parents. Individuals in whom the balance of tissues and functions is not well preserved are less fertile. The very nervous, or the very lymphatic temperaments accompany a lessened reproductive power. The tendency of the age is to a one-sided, intellectual cultivation and undue and artificial development of nervous tissue; hence a comparative sterility. The birth-rate in New England families has been steadily declining, until now it is lower than that of any European country except France. One additional element in this, no doubt, is the habit of delaying marriages—a habit made almost necessary by the more expensive style of living which is demanded, and by what some consider the selfishness of young men who prefer not to sacrifice their liberty to the responsibility and expense of domestic life.

Another indication of family deterioration is the increase of divorces. These were rare a hundred years ago, now they number one to about twelve marriages in New England, while among our foreign populations, who are less educated, and even less moral, the ratio is one to forty or fifty.

Many evidences are brought forward to show that marriage does not accomplish all that it has done or ought to do in preventing adultery. The frequency of the charge of adultery in divorce suits is great, it being made in about one-third of the cases. The increase in late marriages, which leave many more of both sexes exposed to temptation, is an undoubted factor in the alleged increase of licentiousness.

As regards the third object of marriage, "mutual help and company," our author alleges the decrease in the number of marriages, the modes of life and business by which men are kept away from their homes, turning their whole energies in every direction except the making home pleasant. To the New York, as well as New England business man, home is often only a place to eat and catch his breath in during the intervals of business. It is also alleged that New England women are losing their love of offspring and home.

The family life of the American, therefore, according to the above indictment, occurs more rarely, begins later in life, is blessed with fewer offspring, is accompanied with less happiness and less fidelity; is, in fine, less of an institution than formerly. The more artificial attractions of this world have supplanted it.

Dr. Allen's remedy is in an attempt to revive the family spirit again. As the foundation of Church and State, as the institution by which good citizens are made, its preservation, he truly asserts, should be jealously guarded. The clergyman and moralist, the statesman and, by no means least, the physician are urged to use their influence to prevent this physical and family deterioration, which, although perhaps exaggerated by some, unquestionably exists.

THE SUNFLOWER IN MEDICINE.

The sunflower (*Helianthus annuus*) has been, for some time, the object of very serious regard on the part of those who wish not only to live, but to live beautifully. It is just now, perhaps, the most conspicuous ornament of everything not too purely sacred or too rigidly scientific. Medical science is very closely linked with human interests and fashions. It becomes us to live up to these and follow our fellow man (at a decent distance) in his present floricultural vagary. We are somewhat surprised, however, to find that until lately the medical aspects of the sunflower have been almost completely neglected. It is, indeed, reported that several medical students have bought

sunflower pen-wipers, and a rural correspondent informs us, incidentally, that he is raising a crop of the genuine plant for the base purpose of feeding his hens. But this is an inadequate treatment by the profession of the leonine blossoms over which poets sing and ladies rave.

We have to call attention, therefore, to the fact that, medicinally, the sunflower is a thing not to be despised. It is an anti-periodic and a counter-irritant of the best kind. About fourteen years ago an article appeared in this journal, showing that the sunflower, freely planted over malarious districts, had the power of dissipating the miasms. A district upon the Scheldt, in Belgium, was said to have been made quite healthy by the growth of this now supreme form of vegetation. In an address recently delivered by Dr. A. S. Heath before the Farmers' Club, in this city, the utility of sunflowers in keeping off malaria is forcibly urged. Farmers who live near marshes or stagnant water are advised to plant them abundantly around these sources of infection. The advantages, pecuniary and æsthetical, of surrounding one's self with sunflowers, instead of filling the system with quinine, appear to be very great.

The stalk of the mature helianthus, when dried, forms one of the best natural moxæ. The pith contains a considerable amount of nitre, burning slowly and quite steadily. The moxa is not, at present, in vogue, but it must have its fashion again, and there is no time when it could be so easily rendered popular and pleasing. He would be a poor disciple of the beautiful who could not cheerfully endure to be burned a little with art's most popular vegetable expression.

The medicinal value of sunflower oil, or sunflower tea, has not yet been satisfactorily determined. We may look for investigations in this direction from some of our young medical societies. They may find a solid therapeutical basis for the present idolization of a flower which, to the conservative mind, seems to be a good deal of an artistic sham.

TWO CURES OF RABIES ANNOUNCED.

A CASE of singular interest was reported on June 13th to the Academy of Medicine, Paris. M. Denis Dumont, of Caen, asserted that he had cured a case of hydrophobia by subcutaneous injections of pilocarpin. He had scarcely finished his speech when M. Bouley arose and announced that he had the report of another case, under care of M. Dartigues, of Pajol, cured in a similar way.

M. Dumont's case is carefully reported, and his claim deserves attention.

The history of the case is briefly as follows: On April 16th last a mad dog bit three persons, a man, a woman, and a child, all living near Caen, France. The man, a shepherd, thirty-eight years old, was bitten upon the arm. The wound was cauterized with nitric acid, and it rapidly healed. Thirty-four days passed with no especial symptoms. At this time the woman died with all the signs of hydrophobia. The man was told of this. He became much frightened for himself, was very nervous, and could not sleep. Two days later he began to suffer from burning thirst, which he could not quench on account of paroxysmal contractions of the pharynx; from precordial distress and great epigastric pain. On the next day convulsions developed. He rushed from the house and rolled upon the earth, with hoarse cries, attempting to bite everything that came near. He was taken to the hospital. Convulsions set in again, accompanied for a short time by unconsciousness. There was abundant salivation and sweating. Deglutition was almost impossible. Between the attacks the patient spoke rationally, and was conscious of his condition. Bromide of potassium and codeia were given, with no result. The case grew worse. On the next day nitrate of pilocarpin was given subcutaneously three times in doses of one centigramme. There was profuse salivation and sweating, followed by almost immediate relief in the symptoms. By the next day all danger had passed.

M. Dumont considers this case to have been one of rabies, for the following reasons: 1. The course of the exacerbations and intermissions with the accompanying symptoms of intense thirst, dysphagia, hoarse voice, tendency to bite (?), temporary loss of consciousness, clonic and tonic convulsions, all coincided with the known features of rabies. 2. The duration of the incubation, which was thirty-six days. 3. The death, from rabies, of the woman bitten by the same mad dog. 4. The prodromal symptoms ushering in the acute attack. 5. The modification in the appearance of the wound made by the dog. This, during the attack, became livid, opened a little, and poured out a viscid secretion.

M. Bouley reported the case of asserted rabies successfully treated by M. Dartigues, of Pajol. The patient, a merchant, was bitten on the leg by a mad dog. This was on the 29th of July. The wound was cauterized and healed. Sixty-six days passed with no symptoms. He was then attacked with headache and malaise. The same night the symptoms of rabies appeared. Exactly what they were is not, however, said. M. Dartigues was called and at once instituted his treatment, as follows: he gave, within ten minutes, half a milligramme of arsenite of strychnine and the same amount of hyoscyamin, together with one centigramme of bromide of camphor. At the end of half an hour he began to give hypodermics of pilocarpin. He also put the patient in a hot-air bath. He kept up this sweating treatment for five days, when the patient was relieved of all symptoms.

The report of M. Dartigues' case was very incomplete. It was severely criticized by the Academy.

In discussing the question of the value of pilo-

carpin in rabies, it was shown that this drug had been tried in six cases without any favorable result previously to the above cases.

Looking at the question calmly, it is impossible to deny the value of M. Dumont's case, although a doubt might be legitimately entertained as to its really being one of rabies. The case of Dartigues, as reported, is of no scientific value. We cannot say as yet, therefore, that rabies has unquestionably been cured by pilocarpin, though it seems probable.

RECENT CONTRIBUTIONS TO THE TREATMENT OF DIPHTHERIA.

THE constant succession of new remedies for diphtheria is of interest, chiefly because it shows the activity and unrest of the growing science of medicine. We no longer expect any absolute specific, and the wise physician will not abandon his old therapeutic measures without much caution.

In a series of very lengthy articles, contributed to the *Berliner Klinische Wochenschrift*, Dr. Otto Seifert commends the use of chinolin in the treatment of diphtheria. His article is carefully written, and consists almost entirely of detailed reports of cases submitted to this treatment. Donath has asserted that chinolin is a powerful disinfectant, and that even in a 0.2 per cent. solution it prevents decomposition and hinders the development of bacteria, being stronger than carbolic acid, boric acid, alcohol, or sulphate of copper. The tartrate of chinolin is often used because it is more soluble. It is, however, very disagreeable to the taste and smell. Dr. Seifert, therefore, made a five per cent. solution of the pure drug in equal parts of alcohol and water. He also made a 0.2 per cent. solution with a smaller proportion of alcohol. In his cases the strong solution was penciled upon the throat every three or four hours or less frequently, while the weaker solution was used as a gargle, a little of it being sometimes swallowed. The records of the cases show that almost invariably the penciling was followed by a marked decline in the fever, and by a general as well as local improvement in the symptoms. The cases are designated as mild or severe. In nearly every case they got well, but the strength of the evidence for the new drug lies in the fact that the record shows such marked effects always following local applications.

Dr. Theodore Clemens relates in the *Allgemeine Medicinische Central-Zeitung* his method of treating diphtheria with alcohol inhalations. The value of alcohol in diphtheria is admitted, and Dr. Clemens' method is not an essentially new one. He uses a mixture composed of: ℞. Spirit. vini rectific., 120. grammes; chloroform, 15.0; acid salicylic, 10.0; olei lanæ pini, 3.0. This is dropped upon salicylated cotton and the patient made to inhale it for five or ten minutes, every quarter or half hour, or less frequently, according to the symptoms. Dr. Clemens commends his treatment in a general way, without relating cases.

M. Henri Bergeron recently read a communication before the Medical Society of Paris upon the treatment of diphtheria by the inhalation of fluoric acid. This method he had employed, and had made a preliminary report concerning, in 1879. The method is as follows: A small vessel of lead is placed in a water-bath and kept at a temperature of between 90° and 100° F. In the leaden vessel, a teaspoonful of fluor spar and a sufficient quantity of sulphuric acid are placed. The apparatus thus arranged disengages fluoric acid. It is placed near the patient, who is made to breathe with the mouth open. The materials are renewed about five times in the twenty-four hours. Dr. Bergeron claims that all cases treated by this method within the first twenty-four hours after the disease has appeared will get well. In forty cases which he reports, only three died. The discussion which followed the reading of this communication showed a good deal of incredulity toward the new method upon the part of the French physicians.

A Russian physician, Dr. P. Hampeln, of Riga, relates his experience with pilocarpin, cyanate of mercury, and benzoate of soda, all of which have of late been highly vaunted as remedies in diphtheria. He found them all to be disappointing and unsatisfactory. He recommends highly, however, the use of oil of turpentine in severe cases, according to the method described by Bosse, of Donau, in 1880 and 1881. Large doses (℥i. of the pure oil) produced remarkably favorable results in desperate cases, according to Dr. Hampeln's experience.

DEATHS FROM CHLOROFORM.

Two more deaths from chloroform have been reported recently as occurring in London hospitals. As usual, all the necessary precautions were taken and the fatal results were sudden and unexpected. It is, indeed, the old story, in which it is made apparent that chloroform is a treacherous anæsthetic, that it kills without warning, and that there is no condition of the patient, however healthy to outward appearances, which can guarantee the administrator against a most distressing disaster. And yet in England chloroform still continues to be the favorite anæsthetic. Here we have learned not to trust it, and sulphuric ether replaces it almost entirely, save in cases in which it is necessary to induce anæsthesia in very young children and in cases of parturition. It would be well if professional sentiment concerning the positive dangers of chloroform were as sufficiently pronounced in other quarters as in this country. But we learned the lesson early in the history of anæsthesia, and have so far profited by it that many apparently unaccountable deaths have been prevented thereby. The conveniences of administration, rapidity of action, and comparative

agreeableness of the drug to the patient, are more than offset by the chances of occasionally killing the patient as suddenly and as unexpectedly as if by lightning. Happily, here the surgeon who uses chloroform exclusively has to take an extra risk and assume an extraordinary responsibility. In case of accident, he is called upon to give some good reason why he preferred chloroform to ether, or rather, why the use of the latter was, in his opinion, contra-indicated. The majority of fatal results from chloroform in this country have occurred in connection with more or less trivial dental operations, but a sufficient number, few as they are, have been associated with major operations to cause most American surgeons to discard the use of such a dangerous anæsthetic altogether. In former times dentists employed chloroform largely; now, however, in view of the many accidents of death, any dental surgeon who would use the drug with fatal result would be indictable for manslaughter. And a surgeon who should do likewise would not be much better off. This seems to be the correct interpretation of public and professional opinion upon the matter. Why, in view of the extensive experience with ether in all our large hospitals, the same opinions do not prevail abroad, it is difficult to understand. No surgeons in the world use chloroform with more care than do those of England, and yet the accounts of death from the anæsthetic are almost frequent enough to be mentioned under the head of regular news. That we do not have frequent deaths from ether, as used in this country, is saying a great deal for the harmlessness of that anæsthetic. It is safe to say that no equally powerful drug is used more frequently and with less care than is this.

THE SOCIAL POSITION OF THE DOCTOR.—Lay testimony concerning the social position of the doctor in England confirms the statement of Dr. Fothergill, that it is a very poor one. The London correspondent of the *Tribune*, commenting upon the matter, tells the following anecdote: "The wife of a fashionable physician living in Mayfair is responsible for this story. She was in want of a cook and resorted to the advertising columns of *The Times*. One of the advertisers to whom she wrote entered the house, it would appear, without noticing the brass plate on the door which here announces the doctor's residence, but heard on her way up stairs into what manner of dwelling she had been beguiled. She sailed into the drawing-room, and, without preface of any sort, delivered her soul thus: 'If you please, mum, I said partickler in my advertisement that I wanted a situation in a *gentleman's* family, and I won't trouble you no further.' And so sailed out again." The worst of it is that, according to the testimony of New York physicians who have often visited London, the social position of the English doctor is low because it deserves to be. He is in most cases the worst kind of a middle-class Philistine.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 26, 1882.

DR. EDWARD C. SEGUIN, PRESIDENT, IN THE CHAIR.

(Continued from page 104.)

DR. PEABODY also presented a specimen, illustrating the following condition:

INTERSTITIAL MYOCARDITIS, WITH COMMENCING ANEURISMAL FORMATIONS, CAUSED BY ENDARTERITIS OBLITERANS.

The heart was removed from the body of a man, fifty-five years of age, who was picked up in a condition of unconsciousness in the street a few weeks ago and taken to the Chambers Street Hospital. He was moribund on his arrival and survived but a few hours. His pupils were normal, there was no paralysis, his temperature was 101° F., and his urine contained a trace of albumen. No account of his previous condition could be obtained.

The autopsy showed, besides the lesions of the heart, a slight amount of diffuse nephritis, together with congestion, œdema, and pigmentation of the lungs. The brain was normal. The endocardium was generally thickened, and the aortic cusps were similarly affected. The chief lesion, however, was in the muscle of the organ. It had been replaced by connective tissue very largely in two places. The most marked change had occurred between the papillary muscle of the mitral valve and the attached border of the aortic valve. Over a nearly circular area there was a distinctly aneurismal bulging of the septum ventricalorum and also of the left border of the left ventrical. The area of the lesion had a diameter of nearly two inches, and the depth of the sac was fully three-quarters of an inch. There was a similar, but less morbid condition near the apex of the ventricle in the septum—at a point where lesion of this kind was not uncommon. The muscular tissue was in the condition known as brown atrophy. In searching for an explanation of this condition, it became necessary to inspect carefully the coronary arteries. At their origin they do not seem abnormal; but inspection of the primary branch that had been laid open revealed to the naked eye a growth from the intima which partially occluded the vessel. There was a point at which the occlusion became complete. The artery feels like a fine cord beneath the finger.

He had examined, also, the peripheral arteries, and exhibited, under the microscope, sections of the radial artery where it could be readily seen that there was a growth of connective tissue from the intima of the vessel. It was not uniformly thick over the entire circumference of the vessel. In addition to this could be seen an enormous hypertrophy of the muscular coat. This condition, known as *endarteritis obliterans*, is described by Heubner as a syphilitic lesion. There is, however, excellent evidence in favor of its being by no means always of syphilitic origin. There was but little doubt that the lesion was aneurism of the heart, caused by interstitial myocarditis, itself the result of endarteritis obliterans.

Dr. Peabody further presented a specimen that illustrated

RUPTURE OF THE AORTA WITHOUT ANEURISM.

The heart was removed from the body of a lady about fifty years of age. She had been for some years an epileptic, and died suddenly without a struggle and without warning.

At the autopsy the only lesion of interest was in the heart and aorta. It was noticed that the area covered by the pericardium was very large, nearly eight inches vertically by six and one-half laterally. The pericardium was found full of clotted blood, which measured just a pint. Both the parietal and visceral pericardium were covered by a thin layer of recent lymph, indicating a recent acute pericarditis. A rupture of the aorta was discovered, a rupture of all its coats, just behind and on a level with the orifice of the innominate artery, nearly circular in shape, and about the size of the innominate artery. The edges were ragged and fresh fibrin adhered to them. He regarded it as the site of an atheromatous ulcer, whose base became so thin that it finally was unable to resist the force of even a feeble heart His views as to its nature were somewhat strengthened by the fact that there were the lesions of atheroma in all its stages in the immediate vicinity, from the stage of fatty degeneration to the stage of the calcareous deposits. The fat layer on the heart was enormously thick, particularly on the right side. The muscular tissue was yellowish, pale, very flabby, and unusually thin in both ventricles. Examined microscopically, the muscle-cells were found to contain a good deal of fat. The valves were all competent.

There was nothing else of interest in the organs, except that the brain was normal, and that the kidneys showed a small amount of diffuse nephritis.

Dr. Janeway suggested that the cerebral hemorrhage in Dr. Peabody's first case might have been due to rupture of an aneurism formed after embolism, an explanation suggested by the condition of the heart.

Dr. Wyatt asked concerning the frequency of the occurrence of bicuspid aortic valve.

Dr. Peabody thought it of rather infrequent occurrence, as he had records of nearly one thousand post-mortems and had found the condition only twice.

The President asked concerning the unique specimen of aneurism of the heart, if there was not a possibility of its being a malformation.

Dr. Peabody said that it might be congenital. He thought, however, that it could hardly be called a congenital auricle, as it had no connection with the circulation except from the left ventricle.

Dr. Janeway believed it fair to assume that it was an aneurism. He had found cardiac aneurism in about the same region. He had also found one which communicated with the pulmonary artery.

Dr. Peabody asked as to the infrequency of the occurrence of cerebral hemorrhage, from any cause, in so young a subject.

The President said it was more rare than at either of the extremes of life. It occurs more frequently before the age of six years than for the next two or three decades. In early childhood its cause is usually mechanical or dyscrasic, and is not due to miliary aneurisms.

Dr. Janeway referred to cases occurring at the ages of ten, sixteen, and seventeen years respectively. He had seen but few specimens, however, between the ages of six and twenty years.

Dr. Heineman referred to a case occurring in a girl twenty years of age.

EXOSTOSIS OF THE HAND.

Dr. R. Newman presented a specimen removed from the palmar aspect of the ring finger of the left hand. It was not attached to the bone, but to the sheath of the tendon, and when removed the tendon was exposed. The top of the growth before removal had a horny appearance, and was covered by only a thin layer of skin. The wound was healing by granulation. The specimen was referred to the Committee on Microscopy.

Dr. Ferguson presented a mounted specimen illustrating

GREENSTICK FRACTURE OF THE HUMERUS AND COMMINUTED FRACTURE OF THE ULNA.

The bones were removed from the arm of a child fifteen months of age, who was run over by a street-car and brought to the New York Hospital July 7, 1881. It lived six days after the accident, but never rallied from the shock. There were extensive lacerations and contusions of the left arm and forearm, exposing the bones at the site of the fractures. The radial artery was intact.

At the autopsy the left elbow-joint contained some blood. One inch of the upper end of the ulna was comminuted. The fracture in the humerus involved about two-thirds of the shaft; its direction was backward and upward, and was about an inch and a half from the lower end of the bone. The internal organs were normal.

The Society then went into executive session.

THE ELEVENTH CONGRESS OF THE GERMAN SURGICAL SOCIETY.

Held in Berlin, May 31 and June 1 and 2, 1882.

Professor Langenbeck, President.

(Continued from page 109.)

Herr Neuber, of Kiel, read a paper upon the

DISINFECTING AND ABSORBENT PROPERTY OF PEAT.

Since September, 1881, all the wounds at Esmarch's clinic had been dressed with iodoform and then covered with a gauze-bag filled with dried turf-mould. This was very absorbent, and generally in a week the wound beneath was healed. Only in a few cases did pus secrete. Dr. Gaffky had found by experiments that the peat contained numerous vegetable organisms. It delayed the activity of bacterial development but did not impair it. The favorable action of the peat is therefore due to its great absorbent powers and its acid reaction, which keep the wound dry and aseptic. Neuber enumerated several other substances having similar properties; such as bran, sand, ashes, especially from paper, sawdust, etc.

Herr Ranke, of Groningen, had used

THYMOL-GAUZE

as a wound-dressing and got as good results as with the typical Lister method. Thymol, however, soon spoils and becomes ineffective unless it is of good quality at first.

Herr Güterbock, of Berlin, related a case of subphrenic echinococcus cured by a rib-resection. For

twenty days after the operation, echinococci were discharged from the wound and by the mouth.

HERR CREDÉ, of Dresden, reported a case of

SUCCESSFUL EXTIRPATION OF THE SPLEEN.

The patient, a man, aged forty-four, was injured by a brick striking the left hypochondrium ten years before. There resulted a cystic swelling of the spleen, which in late years grew rapidly. It was intended at first simply to remove the cyst, which was found to contain a yellowish fluid and to be separated from the spleen pulp by a membrane. The bleeding was so great that this could not be done, however, and the whole organ was removed. Primary healing followed and the man, after about two months' illness, became well. Credé concludes:

First.—That the spleen can be extirpated without injury to health except a temporary anæmia.

Second.—That its extirpation produces a marked temporary anæmia, with increase of white corpuscles as well as decrease of red.

Third.—That there is at first a temporary swelling of the thyroid gland, probably vicarious. The lymphatics and bones were not affected, so far as could be seen.

Fourth.—All these symptoms disappeared in six months.

In the discussion it was shown that there had been fourteen extirpations of the spleen for leucæmic swelling, all fatal; and three extirpations for cystic enlargement, all with favorable results.

HERR HELFERICH, of Munich, reported a case of

MUSCLE TRANSPLANTATION.

He had removed a large fibro-sarcoma from the biceps of a woman, thirty-six years old, and had filled in the space with a piece of fresh muscle from a dog, sewing it in with catgut sutures. Healing took place and the patient can now bend her arm well. The electrical reactions are also normal.

HERR GLUCK, of Berlin, confirmed Helferich's account and referred to experiments of his own, showing that muscle can be transplanted.

HERR SCHEDE read a paper upon "The Treatment of Collie's Fracture," giving preference to ordinary splints over plaster-of-Paris.

HERR BLOCK, of Dantzig, reported his experiments upon "Resection of the Lung." He had removed lobes from the lungs in fifty to sixty healthy and diseased dogs and rabbits. The operation, which could be completed in five to seven minutes, was well borne. Block considers that the operation might be "indicated" in severe hemorrhages, and for the removal of foreign bodies or local disease.

A discussion was opened by HAHN, of Berlin, upon

RESECTION OF THE STOMACH AND INTESTINE.

Hahn, who had found fecal masses impacted in the colon of a case operated upon unsuccessfully, was inclined to refer the unfavorable result to this cause.

BILLROTH thought it unlikely that the intestinal contents should act injuriously upon the wound and sutures. He believed that the pancreatic juice, however, did have an injurious effect. The lips of the wound must be applied very carefully on this account. Billroth was astonished at the number of cases operated upon for resection, since, in his opinion, among fifty or sixty cases of diseased stomach in not more than one case was an operation indicated. He thought the prognosis more favorable in ulcerating stricture than in cancerous stricture. But he doubted whether the dilated stomach could regain its activity.

GUSSENBAUER confirmed Billroth's opinion as to the injurious effect of the pancreatic juice; also his view as to the unfavorable prognosis in cancerous strictures.

E. HAHN, of Berlin, reported three cases of "rhinoplasty." In the first case, a part of the bony arch remained. He simply formed a new septum by taking tissue from the base of the nose and fastened it with several sutures to the vomer. A good septum was thus formed.

The second patient had a completely trough-shaped nose. He raised up the sunken part, made a cut between the eyes, pulled the flaps down, sawed through the nasal bones and fastened them to the part above. In the third case the cartilages were entirely destroyed and the nose was formed from frontal flaps according to Langenbeck's method.

The same surgeon read a paper upon

THE OPERATIVE FIXATION OF WANDERING KIDNEYS.

He made the cut for this operation from the twelfth rib to the crista ilii through the latissimus dorsi and quadratus lumborum, split the fatty capsule of the kidney and made it fast. One patient was completely relieved; the other still complained of severe pains.

In the discussion LANDAU said that he considered the operation a dangerous one, since the fixing the kidney in an abnormal position was likely to interfere with its functioning, especially in women who might become pregnant. He had seen four cases of movable kidney in emaciated phthisical patients.

He had also seen two cases of congenital movable kidney. But here mobility was normal and stability would have been pathological.

KÜSTER said that he had in one case lessened pains by fixing the kidney.

GLÜCK, of Berlin, related the history of a case of

PYÆMIA CURED

by salicylate of soda, which we considered a specific. The patient had taken ten grammes daily, and four hundred grammes in three months.

BEELY, of Berlin, showed some orthopœdic apparatus; GLUCK showed specimens of thoracic and abdominal aneurisms.

KÜSTER showed a case of habitual shoulder-luxation, also two cases of

GUNSHOT WOUND OF THE SKULL,

with healing, the bullet remaining in the cranium. In the first case the wound was small. It was followed by headache, deafness, and convulsions, which soon disappeared. In the second case, the symptoms were severer and disappeared more slowly.

In the discussion, BERGMANN warned against trepanning in small gunshot wounds.

LANGENBECK had seen five cases of penetrating gunshot wounds of the skull, in all of which there was a cure without trepanning. Permanent mental disturbance resulted in only one instance.

BARDELEBEN had seen four similar cases.

JUL. WOLFF read a paper describing favorable results in resection of the elbow and head of the femur.

BUSCH, RIEDINGER, KRASKE, and RIEDEL read papers upon subjects connected with bone-disease and the surgery of the joints. The papers had only a general clinical interest.

ROSENBACH, of Göttingen, reported some note-

worthy cases of laparotomy from the Göttingen clinic, with exhibition of a specimen of pancreas abscess.

UHDE, of Braunschweig, reported a case of laparotomy for the removal of a wooden plug from the descending colon. It had been pushed into the rectum by the patient, a workman, who was suffering from tænia. The plug was 23.3 centimetres long, and was safely removed.

FISCHER, of Strassburg, read a paper upon

THE TREATMENT OF WOUNDS WITH NAPHTHALIN.

Naphthalin is a hydro-carbon ($C_{10}H_8$). It is developed in combustion and to it part of the preservative action of smoke is due. When perfectly pure, as it should be, it is of a yellowish white color. The author has used it upon animals and found no toxic effects. It has but slight effect upon the blood, being absorbed only in minute amount and passing away quickly by the kidneys. Upon wounds it had no irritant effects. It was a powerful parasiticide and had been used in skin diseases by Fürbringer, of Jena, and others. It was an excellent disinfectant. It might be used in scarlatina and diphtheria, as well as in surgery.

The session closed with a paper by LANGENBECK upon

IODOFORM IN THE TREATMENT OF WOUNDS.

The author spoke strongly in favor of iodoform. His practice was to wash the wound with carbolic acid water, insert a drainage-tube, put in the sutures, and cover the whole with wool filled with iodoform. Compress bandages were then applied. The drainage-tubes were removed in three days, and the wound was generally healed in seven days.

The author thought that the iodoform dressing was an essential progress in antiseptic technique. He had used it most successfully in plastic operations.

MIKULICZ, of Vienna, doubted the genuineness of many cases reported as iodoform-poisoning. He thought the symptoms might rather be due to sepsis. Genuine iodoform-poisoning, on the other hand, was frequently due to faulty methods of applying it.

SCHEDE, of Hamburg, blamed the introduction of iodoform for a deterioration in the hygiene of his hospital. Since its introduction, there had been a large amount of erysipelas.

A number of papers were read by title only, owing to lack of time. The following is a list of some of them:

KOLLIKER, of Leipzig, upon "Knee-Joint Resection."

RUPPRECHT, of Dresden, upon "The Operative Treatment of Club-foot in Adults."

BENNO SCHMIDT, of Leipzig, "Statistics of Herniotomy since the Introduction of Antiseptics."

RIEDL, of Aachen, upon "Non-Traumatic Impermeable Stricture of the Urethra."

MICHAEL, of Hamburg, upon "Permanent Tamponnade of the Trachea."

GUSSENBAUER, of Prague, upon "The Operative Treatment of Impermeable Cardia-Stricture."

PILOCARPIN AND AMENORRHŒA.—Dr. McKeown found in one case that pilocarpin given to a healthy girl who had some eye trouble, produced bloody discharges from the vagina. He suggests the possibility of its value in amenorrhœa.—*Dublin Med. Journ.*

NEW YORK SURGICAL SOCIETY.

Stated Meeting, May 23, 1882.

DR. T. M. MARKOE, PRESIDENT, IN THE CHAIR.

DR. CHAS. K. BRIDDON read a paper (see p. 116) entitled,

CASES OF INTESTINAL OBSTRUCTION, WITH REMARKS ON DIAGNOSIS AND TREATMENT.

DR. A. C. POST thought Dr. Briddon had made one statement which should be qualified, namely, "that in acute obstruction of the bowels cathartics can only aggravate the symptoms." It should be modified so as to read, *as a general rule.* He then referred to a case, already reported, when the subject was before the Society at a previous meeting (see p. 443).

DR. BRIDDON asked if any diagnosis was made in that case, with reference to the cause of the obstruction.

DR. POST said that there was not. The obstruction had continued three or four days, and relief came apparently as the result of the administration of the croton oil.

DR. BRIDDON said that he did not wish to qualify his remarks on that question. He believed that a great deal of mischief was done by the administration of cathartics in these cases.

DR. POST agreed with Dr. Briddon fully in that respect, and wished simply to say that there are cases in which, exceptionally, cathartics do not do harm.

DR. BRIDDON thought they should not be given except in cases of fecal impaction.

DR. G. A. PETERS reported a case of

OVARIOTOMY,

in which complete recovery was the result. It was one more case to be added to the list of successes. On account of the extensive adhesions it was regarded by his colleagues as a very unfavorable one for operation. The patient was forty-two years of age, and said that it was only six months since she first noticed the existence of the tumor. The pathologist had reported that it was a malignant growth. The operation was performed antiseptically throughout, union by first intention occurred in the abdominal incision, and there was only one day when the temperature was above 100° F. The pedicle was broad, was tied in three sections with heavy carbolized silk ligatures, and in addition, as there was some hemorrhage from the stump, another loop was passed around the whole of it.

DR. SANDS had suspected, in several instances, that the silk ligature had caused suppuration. He preferred to use silk instead of catgut if it were entirely harmless to the tissues, but as it is commonly prepared it is more likely to excite suppuration than is catgut. Latterly he had been using silk, as if it were catgut, prepared by first boiling the Chinese silk in water for half an hour or an hour, then transferring it to a five per cent. solution of carbolic acid and boiling for an hour, and then placing the ligatures in a two per cent. solution, where they are kept until needed for use. The cohesion of the silk is not impaired by boiling.

DR. WEIR exhibited specimens of the newer ligatures of Lister, prepared according to the method given in the *The Lancet* for March 18, 1882.

ADENOMA OF THE NECK—VENOUS HEMORRHAGE.

DR. POST narrated a case as follows: At his clinic he removed a tumor from the neck of a boy, five years of age. It was situated high up, near the angle of the jaw. The wound was very deep. Cutting instruments were used only upon the surface tissues, and finally the tumor was separated from its attachments; but just as the last detachment was made there was a gush of venous blood which welled up very freely. The hemorrhage came from a point so high up that he was unable to apply compression to the base, and he therefore resorted to the following method—namely, a carbolized sponge was stuffed into the wound so as to make pressure and the wound was sewed up over it. Over the surface a compress and bandage were applied. This was done at two o'clock and at 5 P.M. there had been no hemorrhage. The compress was then removed, and a loose bandage applied. On the next day, at 5 P.M., he removed the sutures and took out the sponge, and introduced carbolized lint. There had been no return of the hemorrhage, and the patient was doing well.

DR. POST also reported a case (see p. 120) as follows:

RAPID LITHOTRITY.

DR. HUTCHISON presented a number of small urinary calculi and calculous detritus removed from a gentleman seventy years old, by aspiration and lithotrity. The patient showed him at his first visit a small boute filled with calculi removed from time to time from the eye of a catheter, which he had been compelled to use for two or three years to evacuate his bladder. He passes no urine except through a soft rubber catheter introduced about once in three hours. This urine contains an abundance of muco-pus and phosphates. His general health is good. A searcher was introduced into the bladder, but Dr. H. was unable to detect calculus; the prostate is greatly enlarged.

May 15, 1882, five days subsequent to the first, he was anæsthetized, and his bladder again searched without result. He then introduced Bigelow's tube, 28 F., and pumped out the specimens shown in the boute, the largest stone being three-eighths of an inch long. When they ceased to fall into the receiver, the searcher was again introduced, and a stone of larger size was detected, too large to pass through the tube. This was crushed by Bigelow's lithotrite, 26° F., and the fragments evacuated. A portion of the outer shell of the last stone is three-fourths of an inch long. The patient's temperature did not rise above 99°, and he recovered without an untoward symptom.

Dr. H. told the patient before the operation that the development of stone was preceded by cystitis, and was the cause and not result of stone, and that he would probably have a relapse unless some radical treatment was adopted to cure the cystitis. He therefore advised him to have external urethrotomy performed after lithotrity, and a perineal fistula established, to allow the urine to run out as fast as it enters the bladder, so as to give it a physiological rest. The patient declined the cutting operation, preferring to take the risk of a second litholapaxy if it should become necessary. Dr. H. said that the special interest of the case was that by means of Bigelow's aspirator he was enabled to bring the calculi out of their "hiding-places," and remove them, when he had been unable to find them with the searcher, showing that the method was sometimes valuable as a means of diagnosis.

DR. WEIR exhibited two calculi,

(1) XANTHIC-OXYD CALCULUS—(2) CYSTIC-OXYD CALCULUS.

The *cystine* calculus weighed 170 grains, and was found in the *kidney* of a man over seventy years of age, who died of prostatic obstruction, hemorrhage from the bladder, with a villous prolongation of the mucous membrane. Since obtaining it he had found records of sixteen cases. At first he thought the specimen was unique.

The *xanthic*-oxyd calculus weighed 43 grains, and came from quite a young person, who had had symptoms of renal colic. After an aggravated attack on the 11th of November, 1881, she was suddenly relieved of pain, and on the 22d of November, the calculus, $\frac{98}{100}$ of an inch long, and one-half inch in diameter was expelled from the urethra. There was nothing in the history of the case to account for the xanthic-cxyd. There are only eight specimens, with this one, in existence.

The Society then proceeded to the transaction of miscellaneous business.

Correspondence.

UNIFORM MEDICAL LEGISLATION.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: I have read with much pleasure the editorial in the RECORD of April 15th regarding "State Examinations for Licences." I had previously read the proceedings of the New York State Medical Society wherein the question was brought up and discussed. The question of legislation for controlling the practice of medicine, in a government like ours, is open to the same objections and obstructions as in the matter of prohibition, or the social evil. In the absence of a strong central power, each State has the entire settlement of all such affairs, and the condition of public sentiment exercises a controlling influence. The result is that action taken in one State is entirely inoperative in the territory of its next neighbor, and the beneficial effects of legislation (if any) are deprived of much of their efficiency. It is also a very serious question whether any individual State law would be of any real service in the State where enacted—however good the law might be—by reason of the manner of the execution of the same. California has had an experience in medical legislation which, I think, all unprejudiced physicians must acknowledge has put the profession on this coast back twenty-five years. The bill provided that the State Medical Society should appoint a medical board of examiners, before whom every person desiring to practise medicine in the State should appear. The *bona fide* possession of a diploma from a recognized medical college entitled the possessor to a licence from the board of examiners, which licence being duly recorded in the county in which the person desired to practise, gave the holder legal right so to do. The bill further provided that prior to a certain date all persons practising without a diploma could appear before the said board of examiners and upon passing a satisfactory examination should be given a similar licence to practise.

All this was well enough in theory, but when it came to the passage of the bill it was found that

there were so many friends of homœopathy and eclecticism in the Legislature that certain compromises had to be accepted, so that the bill as finally passed provided that each State Medical Society should have authority to appoint its board of medical examiners. As a result of this law five boards of examiners came into existence—one of the regular profession, two factions of the homœopaths, one eclectic, and one semi-defunct State Society which was resuscitated by the absolutely irregular element, the venereal advertisers, etc.

It followed as a matter of course that every practitioner in the State, regular or irregular, received a licence to practise, and all were placed on an equal footing before the law. No matter what amendments may follow, the great evil has been done, and nothing but time can remedy it.

There is no question but that the over-crowded condition of the profession, and the almost countless irresponsible schools, adding yearly large numbers to the multitude of doctors, demand sharp and energetic measures for the protection of the profession, as well as of the community at large; for competition has already become so great as to threaten the life of the profession as such, and degrade it to the level of trade and "cheap John" shops.

The action of your own State Society recently in attempting to declare "limits off" in the matter of consultation, although largely in the interest of consultants and specialists, clearly enough indicates the underlying pressure which could allow for a moment the consideration of such questions.

Unquestionably the first thing to be done is to secure a uniform standard of education, and this so high as to at once diminish the supply. Can any one suppose for a moment that the most heroic efforts of a single State in this direction will control the evil? He must be a very sanguine person who thus believes. The regular profession has been so blind to its own interests in the past, that without entering upon any discussion as to the causes, the schools of Homœopathy and Eclecticism have become powers in the land, and in my judgment it would be perfectly futile to endeavor to secure the enactment of any general laws controlling the practice of medicine and medical education in any State in the Union without taking these factors into consideration. How then shall these evils be met? I think I can see two ways, provided the profession will work harmoniously: one by Congressional and State legislation, the other without legislation at all, and this I would consider much the most preferable. The first, in brief, would be to act in concert with the Homœopaths and Eclectics to secure uniform State legislation in every State in the Union, for the appointment of a State board of examiners, which shall examine all candidates for the degree of Doctor of Medicine in the schools of the respective States, in all branches of medicine except Materia Medica and Therapeutics, the students of the different schools being examined in these branches by a supplemental board, in accord with the tenets of such schools. In addition to this State legislation, to have Congressional action for the appointment of a central board of examiners at Washington, which should have general supervision of the entire subject.

At the recent session of the California State Medical Society, a clause of a proposed new medical bill provides that the State Board of Examiners shall be made up of regulars, homœopaths, and eclectics, not for the purpose of examining the students of the schools for degrees, but for the granting of licences to practise. I am strongly opposed to any such amalgamation, and therefore turn gladly to a consideration of my second plan, which is uncomplicated with any connection outside of the broad field of medicine, and requires no legislation. First, let the National Medical Association, in connection with the Medical Corps of the Army and Navy of the United States, appoint a central or national board of medical examiners. Second, let this board, in consultation with the medical schools and State medical societies of each State, appoint a State board of medical examiners for the determination of a standard for the conferring of all degrees. Third, ignore all medical schools and their graduates who decline to agree to such action. Of course much detail has to be considered in carrying out such a plan, but I am convinced it would be practicable, could be quickly enforced, and would more rapidly than any other way shut up three-fourths of the institutions that are now granting medical diplomas. The standard would at once be placed where the community would recognize its value, and all these side issues could be safely left to their own fate.

I remain very respectfully yours, etc.,

A. M. WILDER,

Late Surgeon and Bvt. Lt.-Col. U. S. Vols.: Prof. of Ophthalmology and Otology, Med. Dept. Univ. of Cal.

MICROSCOPICAL APPEARANCE OF GUITEAU'S BRAIN.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—We submit an account of the microscopical appearance of portions of Guiteau's brain. As will be seen, nothing which we can regard as important, bearing upon his mental condition, was found. Further, minute research and description would, we believe, be of interest only as a scientific record of the appearances of a historic organ.

Pieces of brain from the left frontal lobe, the right central convolution, the cerebellum, and a piece of the spinal cord just below the medulla were obtained about five hours after death, and three and a half after the opening of the cranium. These pieces were placed in seventy per cent. alcohol for twenty-four hours then in absolute alcohol until sufficently hard to cut.

Over one hundred sections were made and stained in various fluids, chiefly in Bismarck brown, carmine, and hæmatoxylon. Sections were also stained in osmic acid, aniline blue, Lugol's solution, vesuvin, etc. Other sections were soaked in ether, and in concentrated acetic acid.

These various methods were employed chiefly in order to determine positively the nature of certain peculiar bodies seen under the microscope. They were quite numerous, but were mostly in the white matter. They were generally round in shape, but sometimes appeared in agglutinated masses. They were somewhat translucent, and measured from $\frac{1}{1800}$ to $\frac{1}{300}$ inch in diameter. Some perhaps were smaller. They had the appearance of not being incorporated in the brain-tissue itself. They stained with Bismarck brown, vesuvin, and gave a rose-red color with aniline blue—this being usually considered a reliable test for amyloid matter. But they were not stained with iodine, even after soaking sections twenty-four hours in water to remove the alcohol. They were not dissolved by soaking sections half an

hour in ether and they were not stained by osmic acid. Hence, they were apparently not fat. They were not dissolved in, but were brought out strongly by soaking sections in strong acetic acid, a substance which dissolves colloid matter.

These bodies were found in sections from the frontal lobes, central convolutions, and spinal cord. We saw none in the cerebellum; but only a few sections were made of this part. We regard them as post-mortem products. One of the writers has sections from the spinal cord of a man who died from tetanus which show apparently similar bodies. Certain writers on cerebral pathology have described similar bodies as being "proteinaceous" and as either post-mortem or the result of chronic brain disease. The aniline reaction was very striking, and might perhaps justify an opinion that they are amyloid bodies, though they gave no iodine reaction.

The writers observed occasional thickened blood-vessels in the cortex. No other change of interest was noted. The perivascular spaces, the cells, the nuclei, all presented no abnormalities which we could detect. There were no aneurisms, and no pigmentation. The large motor-cells from the right central convolutions (one of which was small) were abundantly present, and were normal in appearance.

A minute description of the different parts as well as a drawing of some of the sections have been made, but it does not seem worth while to ask your space for their insertion.

Our examinations were made in large part at Prof. Satterthwaite's laboratory, and we are indebted to Drs. W. H. Porter and E. C. Wendt for suggestion and assistance in studying and preparing the sections.

WM. J. MORTON, M.D.
C. L. DANA, M.D.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 16, 1882, to July 22, 1882.

CORSON, J. K., Capt. and Asst.-Surgeon. Relieved from duty in Dept. of Arizona, to proceed to Philadelphia, Pa., and, on arrival, to report by letter to the Surgeon-General. S. O. 164, A. G. O., July 17, 1882.

CARVALLO, C., Capt. and Asst.-Surgeon. Relieved from further duty in Dept. of the Platte, and to report by letter, at the expiration of his present sick leave of absence, to the Surgeon-General. S. O. 164, C. S., A. G. O.

HOPKINS, WM. E., 1st Lieut. and Asst.-Surgeon (recently appointed). To report by letter to the Commanding General, Dept. of the East, for assignment to temporary duty. S. O. 164, C. S., A. G. O.

BARROWS, CHAS. C., 1st Lieut. and Asst. Surgeon (recently appointed). To report in person to Commanding General, Dept. of Arizona, for assignment to duty. S. O. 164, C. S., A. G. O.

MUNDAY, BENJ., 1st Lieut. and Asst.-Surgeon (recently appointed). Assigned to temporary duty at Willet's Point, N. Y. S. O. 164, C. S., A. G. O.

WILSON, GEO. F., 1st Lieut. and Asst.-Surgeon (recently appointed). To report in person to the Commanding General, Dept. of the Columbia, for assignment to duty. S. O. 164, C. S., A. G. O.

OWEN, JR., WM. O., 1st Lieut. and Asst.-Surgeon (recently appointed). To report in person to the Commanding General, Dept. of the Columbia, for assignment to duty. S. O. 164, C. S., A. G. O.

EGAN, PETER R., 1st Lieut. and Asst.-Surgeon (recently appointed). Assigned to temporary duty at the recruiting depot, David's Island, N. Y. S. O. 164, C. S., A. G. O.

WAKEMAN, WM. J., 1st Lieut. and Asst.-Surgeon (recently appointed). Assigned to temporary duty at Columbus Barracks, Ohio. S. O. 165, C. S., A. G. O.

EVERTS, EDWARD, 1st Lieut. and Asst.-Surgeon (recently appointed). To report in person to Commanding General, Dept. of the Columbia, October 1, 1882, for assignment to duty. S. O. 164, C. S., A. G. O.

Medical Items and News.

ALCOHOLIC ANÆSTHESIA.—Dr. L. D. Mason, of Fort Hamilton, in a paper on this subject, describes two forms of alcoholic anæsthesia, one general and temporary, and due to acute poisoning, the other local and more permanent, and the result of prolonged use of the drug. Cases are cited showing the genuinely anæsthetic condition produced in each form.

DR. JUSTIN HAYES.—In a recent notice of Dr. Hayes' treatment of diphtheria, an error was made in the name of the town mentioned. It should have been Shalersville, O., instead of Slatersville.

THE TREATMENT OF CARBUNCLE.—Dr. A. C. Post writes: In my report on the local treatment of carbuncle, on p. 44, I am represented as saying, "Considerable arterial hemorrhage occurred from the edges and bottom of the carbuncle when divided." It should read "Considerable arterial hemorrhage occurred from the edges and bottom of the carbuncle while I was examining it, but after the free incisions were made, the blood soon ceased to flow, apparently in consequence of the relief of tension of the engorged parts afforded by the incisions." You will perceive that the chief interest of the case lay in the fact that the hemorrhage was checked by the incisions, and not produced by them.

THE LATE DR. JAMES R. WOOD.—At the monthly meeting of the Medical Board of the Charity Hospital, for July, held at the Academy of Medicine, the following resolutions were passed:

Whereas, At the end of a long life, devoted to the relief of human suffering and the exaltation of the profession of which he was an honored and devoted member, James Rushmore Wood, M.D., LL.D., a consulting surgeon of this hospital, has been taken away from us; and

Whereas, When such a life is ended, it becomes those who have been associated with, and have profited by his labors, to give official expression to their sense of the great loss they have sustained; therefore,

Resolved, That we, the members of the Medical Board of the Charity Hospital, appreciating his noble and generous character, his unselfish devotion, his large-hearted and open-handed charity for the poor and distressed, and believing that his best

eulogy and most lasting monument will be found in the record of his life, here add our tribute to his memory, our acceptance of the value of his example, and our pride that his name and his labors have a place in the records of our profession, tendering to his family and friends our sympathy in their grief.

Resolved, That these be a part of our minutes, and be forwarded to the widow and the Honorable Board of Commissioners of Charities and Correction.

J. F. Ferguson, M.D.,
Joseph W. Howe, M.D.,
W. M. Chamberlain, M.D.,
} *Committee on Resolutions.*

W. T. White, M. D., *President.*
Edward S. Peck, M.D., *Secretary.*

Consistency.—Dr. Eugene Grissom was elected a vice-president of the American Medical Association at its St. Paul meeting. Dr. Eugene Grissom is a member of the Association of Insane Asylum Superintendents. This association has, besides other homœopathists, as a member, Dr. Selden H. Talcott, Superintendent of the New York State Homœopathic Insane Asylum, President of the State Homœopathic Society. The Judicial Council of the American Medical Association excluded the New York State Medical Society delegates for having a code not in accord with the association. This action was certainly defensible on the ground that until the law of the American Medical Association was changed, all members should comply with it, but then how much consistency is there in electing as vice-president one who is a member of a medical association which admits homœopathists, and thus conflicts with the association's code.—*Chicago Med. Review.*

Nothnagel has been chosen to succeed the late Professor Duchek.

Vogt has been called to the Surgical Chair in Greifswald, in place of the late Professor Hueter.

Carbolic Acid Treatment of Piles.—Dr. H. Z. Gill, in a monthly report of the Southern Illinois Penitentiary, says: "There have been more than a dozen cases of piles treated by carbolic acid hypodermic injections. Many of them were of years' standing, and they now, even the worst, declare themselves entirely cured. The amount of acid injected was from five to ten minims, dependent upon the size of the tumor. The acid used was the crystallized, with just enough glycerin to hold it in solution. The operation was made slowly, and the needle slowly withdrawn. The course has been mild in most cases, and the results have been entirely satisfactory."

Dr. Chiari has been called from Vienna to the Chair of Pathological Anatomy at Prague left vacant by Klebs.

The Third Centennial Jubilee of the University of Wurtzburg will be celebrated on August 1, 1882.

Koch's discovery of the tubercle bacillus has excited the interest of the German Emperor, who has asked to have specimens shown him.

The Tenth German Medical Congress met in Berlin, June 30th, July 1st and 2d.

Pilocarpine in Detachment of the Retina.—Dr. Eugene Smith, in his report of the Eye and Ear Department of St. Mary's Hospital, Detroit, says: "During the past year I have had opportunity to test the use of pilocarpine or jaborandi in five cases of *detachment of the retina*. Success has followed its use in three cases, and slight improvement in two, and we have at last found a remedy for many cases of what was till recently considered an incurable condition."

The Living Skeleton, exhibited for some time past in a museum in this city, died recently. He was found to have had phthisis, and was not so very thin after all. He weighed one hundred and six pounds, instead of fifty, as advertised.

Prosecuting Irregular Practitioners. — The County Medical Society has brought suit against another alleged quack, Dr. W. C. Harbison.

Syrup of Bromide of Chloral is a successful pharmaceutical preparation. A fluid drachm contains five grains of the compound. This five grains contain nine parts of chloral to one of pure bromine.

A Good Departure.—In London has been founded a national society for the suppression of juvenile smoking. One of the leaders in the movement is Dr. Benjamin Ward Richardson. Letters in approval of the society's aims were read at the first meeting from the Earl of Aberdeen, Mr. Samuel Morley, and others. Dr. Richardson said the use of tobacco by the young was a grave and increasing evil, and that the effects of it on them were destructive both to mind and body. He was convinced that the need for the society was large and real.

Is the Strawberry a Dangerous Fruit?—The Hon. Frank Fuller, at a recent meeting of the newly organized National Sanitary Association, denounced the strawberry as unhealthy and dangerous. He claimed that the seeds were liable to irritate the bowels, and especially to get into the appendix and cause typhlitis. The charge was not substantiated by any facts, and we doubt if medical experience will sustain it. The *Times*, commenting upon this matter, says: "The Hon. Frank Fuller could not think of deriding the colicky gooseberry, or the seedy and deceptive blackberry, or even the suspicious and unbuttered watermelon. Slander loves a shining mark. The summer sanitary philosopher selected the paragon of small fruits to be maligned as parent of serious forms of intestinal lesion and the creator of fistulous openings. The Hon. F. F. thinks to achieve eminence as did the youth who fired the Ephesian dome. But the strawberry will bless the world long after the fame of this midsummer maunderer has perished."

Dry Treatment of Mucous Membranes.—At a recent meeting of the St. Louis Medico-Chirurgical Society, the dry treatment of mucous membranes was much advocated. It consisted in blowing borax, bismuth, iodoform, or astringent powders upon such membranes as could be reached. Or in the case of the vagina or rectum, in introducing hollow suppositories containing the proper kind and amount of powder.—*St. Louis Courier of Med.*

Insanity and Responsibility.—A man can be insane and yet can make a valid contract, a valid will, can do his regular business, providing his insanity or delusion of whatever form does not interfere. Vice and insanity, disease and health, may be commingled, but when any man known to be insane commits a great crime the presumption is that that

crime is, in whole or in part, the result of the insanity. When a noted criminal becomes insane, his subsequent acts are far more the result of his insanity than his evil disposition. For vice is a pigmy, but lunacy is a giant. Vice drags a man down, but lunacy makes a child of him—makes a brute of him—makes a demon of him. So well is this understood that it would generally be impossible to convict an insane criminal. The highest penalty of responsible crime ought not to be inflicted on a man known to be insane, even if he be naturally vicious. —*Beard.*

Constipation in Infants.—The following are some of the remedies found useful by Dr. D. H. Cullimore (London *Lancet*): 1. A pellet of butter and brown sugar or treacle every morning fasting, or a little raspberry jam. 2. The morning insertion into the rectum of a conical piece of white curd soap about two inches and a half long. It must be first dipped in warm water, held *in situ* for five minutes, and withdrawn. 3. Daily friction over the body, from the right iliac region along the course of the gut, with a salad oil. In India I have used cocoanut oil advantageously. Cod-liver oil is very useful when its smell is not objected to. Assiduous friction without any unguent is often useful. Patience, however, is necessary. A teaspoonful of fluid magnesia in the food is a good plan. Tomato jelly is sometimes used in India with benefit. Whatever plan may be adopted it is well to supplement it with the internal administration of half a drop of tincture of nux vomica three times a day; a quarter of a drop is sometimes sufficient. Minute doses of sulphur also answer well.

The Skull of Kant.—Kupffer and Bessel give a description of the skull of the philosopher Kant, which is summarized in the *Journal of Neurol. and Psychiatry*. The brain exhibited the frontal suture, which has ordinarily, though with no good reason, been held to be a sign of low development. Kant was only a little over five feet high, and of delicate frame, yet his cranial capacity was 1,740 cubic centimetres. Only two and a half per cent. of the German race, which is said to have the greatest cranial capacity, exceed 1,700 cubic centimetres. The head was long, the forehead not very broad. The most remarkable feature was the disproportionately great development of the upper fossa of the occiput, which receives part of the occipital lobe. In the average skull the occipital fossa is to the cerebellar as 1:1 or 3:2; in Kant's skull, however, the proportion was 2:1. Kant had, therefore, a voluminous brain, with relatively small frontal lobes and cerebellum.

Dry Treatment of Caries.—Dr. Engelmann (*St. Louis Courier of Medicine*) describes a number of cases of caries treated simply with cotton, in the children's hospital in Paris some ten years ago. The method of treatment resorted to for years, and for which they claimed absolutely perfect results, was to bandage the entire limb very thickly in cotton, which being once put on was not removed for six months, perhaps, and when it was removed the once foul suppurating wound had completely healed.

Application of the Cold Douche in Blennorrhœa Neonatorum Complicata.—Dr. O. Paulsen, of Hamburg, describes (*Berlin Klinisch. Wochenschrift*) the troubles attending the treatment of severe cases of ophthalmia in infants. The very rapid secretion of pus and the spasmodic closing of the lids are the factors which especially make it difficult to treat these cases satisfactorily. Dr. Paulsen thinks that the cold douche remedies these difficulties, however. In severe cases this must be repeated every ten or fifteen minutes, then every half hour or hour, each application lasting two or three minutes. It is surprising, says Dr. Paulsen, to see how quickly the tension of the lids relaxes and the conjunctivæ become visible.

Dr. Samuel Sexton has been elected a Life Member of the New York Institution for the Instruction of the Deaf and Dumb.

The Taliacotian Operation.—Mr. Wm. Stokes, of Dublin, recently performed successfully the Taliacotian operation upon a young man, who had accidentally had a large part of the nose shot away.—*Dublin Med. Journal.*

The Cartwright Prize of $500, of the Alumni Association of the College of Physicians and Surgeons, New York City, will be awarded in May, 1883, to the best medical essay, the subject to be selected by the writer. This prize is open to universal competition, and the conditions of its award are that the essays presented must contain the results of original investigations made by the writer, and be handed in to a member of the Prize Committee on or before April 1, 1882. The committee consists of Drs. Weir, Seguin, and Partridge.

Humanized Virus.—Dr. F. H. Darby, of Morrow, Ohio, believes that humanized virus of two, three, or even four removes is the best. The objection of slowness put forward against the humanizing method he does not consider as of any weight in the practice of the active physician. The liability of disseminating syphilitis and other diseases is *nil*, at least in rural districts where family histories can be traced back for ages by the doctor. Owing to the gradual deterioration of virus propagated by the humanizing process, arm to arm vaccination should not be exclusively relied upon; but neither would it be proper to pin one's faith to bovine virus alone. The mean, then—an occasional reversion to the cow—is the course to pursue. Bovine virus is exceedingly prone to deteriorate in short time. Spreading it in thin layers is no doubt the secret of the lack of success so commonly complained of.

Medical Practice on the Frontier.—Dr. R. C. Newton, U.S.A., of Fort Cummings, New Mexico, sends us the following account of frontier medical practice:

"About a hundred miles north of here, there is a mining camp called Fairview. This place boasts an individual who keeps a saloon and restaurant, and at the same time practises *medicine and dentistry* extensively throughout the Black Hills mining district. The legends on his sign, 'Dock's Saloon' and 'Meals at all hours,' give all desired information. The former is pregnant with meaning, as it is the doctor's shingle and the saloon-keeper's sign combined. 'Dock's' businesses are well advertised in various adjoining towns, or camps as they are here called, by signboards reading 'Go to Dock's, Fairview, for a square meal.'

"One of the frequenters of this saloon, a friend as well as a patient of its illustrious proprietor, from too liberal use of 'Dock's' peculiar brand of whiskey was overtaken by a severe stroke of paralysis. 'Dock,' who had really been chiefly instrumental in bringing on this attack, was at once summoned as medical adviser. He pronounced the case hopeless, and *recommended a strong dose of strychnine*,

which would, he said, put the patient out of his sufferings.

"He was persuaded not to adopt so heroic a course of treatment, and was led to call in consultation another medical light from the neighboring town of Robinson. This town exists principally upon paper. However, its medical man came and recommended the administration of some form of mercury in an enema, as the best method of treatment. They refused an offer of a bed made by a friend of humanity, who found the poor patient lying upon the dirt floor on a few blankets, saying in effect that it was not worth while to bring the bed, as the patient would not live until morning.

"The gentleman becoming much disgusted with the proceedings, and having persuaded an old miner to join him, visited the sick man, threw away all his medicines, put the nurse under the strictest orders (which mean something in a mining camp) not to administer another particle of 'Dock's' medicine, and gave the paralytic a dose of castor-oil, the need for which was very apparent.

"This interference was followed by the happiest results. The unfortunate man, who was apparently at the point of death, soon began to improve: he regained his intelligence, and some power over his limbs, although he is still partly aphonic. He could soon take exercise in a cart, and seemed to be doing well in every way.

"'Dock' boasted very boldly of the recovery as entirely due to his skill, asserting that he knew that if the patient could only retain the remedies prescribed recovery was certain. Apparently fully convinced of the beneficent effect of his medicines, and particularly of his whiskey (the vileness of which I have already hinted at), 'Dock' persuaded the nurse to bring the patient daily to his saloon to imbibe the stimulant in excess, and finally, by his seductive manner, he got the patient to remain for several days at the saloon. This course led the miners, in order to save their unfortunate comrade's life, to club together and send him to the hospital at Santa Fé.

"It is much to the credit of the miners, most of whom are not yet rich, that they contributed liberally to support the sick man after his rescue from this medical phenomenon."

A Peculiarly old Surgical Operation.—Dr. Wm. S. Forbes, of Philadelphia, recently cut the accessory tendons of the extensor tendon of the ring finger. The operation was performed upon a pianist, and enabled him to play much better. The operation was a success, but it is not new or peculiar. As a rule, it does not add to the strength and mobility of the finger.

Iodoform and Listerism.—Professor Lister has recently been making some trials of iodoform and is using it considerably, according to the *British Medical Journal*, in his dressings. Like others, he finds it more convenient than other ordinary antiseptics for the treatment of local sores, for introducing into chronic sinuses or into scrofulous joints after incision; but it is not easy of application to an amputation or to most other operation wounds; and is quite unsuitable for use with the spray. For this reason Professor Lister still operates under the carbolic acid spray, though he now seems to attach rather less importance to its continuous use, and will stop it, for instance, for a short time during an operation if the cloud it produces be found to interfere with a clear view of the wound. The dressings used consist of cotton-wool impregnated with iodoform, and the drug itself is, in certain cases, powdered over the wound from a sprinkling-box. "Iodoform wool" has also been extensively used at University College Hospital. The great difficulty encountered in preparing the wool is to obtain an even distribution of the iodoform. The desired end is best obtained by treating the powdered drug with ether, in the proportion of about eighty-eight parts of ether to eight of iodoform. In about four pints of this mixture, half a pound of fine, clean cotton-wool is soaked for a short time; the wool is afterward placed in a drug-press. About three pints of ether can be squeezed out, and, when dry, the wool contains about ten per cent. of iodoform. The same objection is made against this wool as against salicylic wool—namely, that its use spreads about the room an irritating dust, with this further disadvantage, that the odor is to most people very offensive. A little glycerine added to the ether used in its preparation, checks the former tendency, and the latter drawback is minimized by the addition of eucalyptus oil. The wool ought to be stored in air-tight boxes, and not handled more than necessary before use.

A Bogus Medical College.—At a meeting of the Jasper County Medical Society, held in Carthage, Mo., on Tuesday, April 4, 1882, the following preamble and resolution were unanimously passed:

Whereas, The Jasper County Medical Society, having been credibly informed that a so-called Joplin College of Physicians and Surgeons has been issuing diplomas to various persons without a proper course of practical anatomy, and so varying from the established rules of reputable colleges as to bring discredit and ridicule upon the good standing of the profession generally; and

Whereas, We are also credibly informed that the institution above mentioned has no legal existence, and its graduates are liable to indictment for practising medicine contrary to law in Missouri; therefore be it

Resolved, By the Jasper County Medical Society in regular convention assembled: That we will not fraternize with any of the professors or graduates of this so-called Joplin College of Physicians and Surgeons until they have complied with the rules of *regular* medical colleges in good standing.

Bovine Vaccination.—Dr. Samuel C. Benedict, of Athens, Ga., writes: "The sayings of 'Speculum,' in issue of May 27 of your valuable journal, accord in so many respects with the opinions formed from my own experience that I wish to add my 'Yes' to them.

"Since February 1st I have vaccinated with *points* about four hundred person. Nearly all of these points have been obtained from Petit's farm, at Cleveland, Ohio, and have proved more satisfactory than those from other farms.

"The percentage of good results with these points has been about 80. Quite frequently some one of those upon whom a point had been used has shown a raspberry sore, *not* a true vaccine sore. This was in every instance the case in a lot of Petit's points obtained four weeks ago, and used within a week after receiving them. This result, of course, is very unsatisfactory, for what protection is there to a person with such a sore, one which many may think a good result and expose themselves, feeling safe. These raspberry sores are due to what? I have seen them in children having no signs of pre-

vious vaccination. What produces such results? About the same time that the last lot of points were used I was requested to vaccinate the hands working on a railroad extension. The virus used in these cases was a scab from a healthy arm, which scab was made from a point. Out of forty-seven vaccinations thus made, *forty-four* have proved successful, the results being very satisfactory indeed. All of the forty-four have shown a polyvesicular sore, enlargement of axillary glands, and, in most, marked constitutional symptoms. From the experience I have had with points, and with scabs *once removed* from the bovine virus, and the results I have seen in the good hands of others, I would to-day unhesitatingly use such a crust in preference to points if the urgency for a successful vaccination at first trial demanded it. I like to use the points; they are convenient, neat, and efficient, as a rule, *when fresh*, but this very uncertainty as to their age and purity, even from the best producers, is an objection; and consequently a well-selected, well-pulverized scab, 'once removed,' seems to me safer, because *surer*."

THE PHYSIOLOGIST'S NIGHTMARE.

By E. C., M.D.

POET LAUREATE OF THE ROMAN MEDICAL SOCIETY.

Once upon a midnight dreary, while I labored, weak and weary,
Ever delving after knowledge new in biologic lore—
While I nodded, nearly napping, suddenly there came a tapping,
As of some one gently rapping at my laboratory door.
"'Tis some student there," I muttered, "at my laboratory door—
Only this and nothing more."

Open here I flung the shutter, when, too dread for lips to utter,
In there stalked a ghostly likeness of a form I'd seen before:
Not the least obeisance made he; not a minute stopped or stayed he;
But with mien of lord or lady posed himself before my door:—
By the pallid dusty panels of my laboratory door
Posed and looked, and nothing more.

Then this gloomy thing beguiling all my keen wit into smiling,
By the woe-begone expression of the countenance it wore,
"By thy chin all shorn and shaven, thou," I said, "dost look a craven
Ghastly grim resemblance graven of a form I've known afore—
Tell me what thy fateful name is, if 't be one I've known afore!"
Quoth the Spectre, "Bergh, be gorr!"

And the Spectre, leaning lonely 'gainst the panelled door, spoke only
That one phrase, as if his soul in that one phrase he did outpour.
Nothing farther then he uttered, not a syllable he muttered—
Till, a little bored, I spluttered, "Other bores have gone before—
On the morrow *he* will leave me, just as bores have done before."
Then the thing said, "Nevermore."

Then, methought, the air grew denser, and the Spectre's wrinkles tenser
As he tapped his toes exultingly upon the sanded floor.
"Wretch," I cried, "whoever sent thee, let this beer-mug now content thee,
Quaff, oh, quaff the malt nepenthe, and be jolly, I implore—
Quaff the foaming malt nepenthe, and be jolly, I implore!"
Quoth the Spectre, "Nevermore!"

"Nuisance," said I, "thing of evil!—nuisance still, if Bergh or devil!—
By the charnel-room above us, by the lecture-hall before,
Tell this soul in deep dejection, if, on serious reflection,
You'll permit of vivisection, if we do it without gore—
Let us practise vivisection, if no agony or gore!"
Quoth the Spectre, "Nevermore!"

"Nuisance," said I, "thing of evil!—nuisance still, if Bergh or devil!—
Surely, though, the boon of Jenner you will hardly dare ignore.
Your humanity addressing, then I pray you, acquiescing,
Grant, oh, grant us still the blessing of the Vaccinating Corps—
Grant surcease of Death's foul horror by the Vaccinating Corps!"
Quoth the Spectre, "Nevermore!"

"Be that word our sign of parting, Bergh or fiend!" I shrieked, upstarting,
"Get thee back into the bigotry of Night's Plutonian Shore!
Leave no horse-hair as a token of the curse thy soul has spoken!
Leave my loneliness unbroken!—get thee gone from off my door!
Take thy cant from out my heart, and take thy form from off my door!"
Quoth the Spectre, "Nevermore!"

And the Spectre, truth defying, still is lying, still is lying
On the subject of the blessings wrought by biologic lore:
And his eyes have all the gleaming of a madman's that is dreaming,
And the gas-light o'er him streaming throws his shadow on the floor,
And the buds of knowledge blighted by that shadow on the floor,
Shall they blossom—any more?

The Influence of the Central Nervous System on the Regulation of the Animal Heat.—A. Bókay (*Pester Mediz.-Chirurg. Presse*), on the ground of certain experiments upon dogs, concludes (1) that there are certain cortical centres, irritation of which causes a rise in the temperature of the body; (2) that these centres are in the anterior and upper parts of the central convolutions; (3) that certain parts of this area cause, on irritation, local rises in temperature, and that there are three temperature centres for the front and hind limbs, etc.; (4) that there are also heat-inhibiting centres; (5) that the vaso-dilator system interposes in this increase of temperature.

These conclusions verify, to a certain extent, Wood's experiment. The conclusions are much broader, however, and not so carefully substantiated.

Death by Chloroform.—A case of death by chloroform recently occurred in the practice of Dr. Kinlock, of Charleston, S. C. The patient was a young lady of wealth and high social position, who was suffering from some uterine trouble. It was necessary that a slight operation should be performed, and chloroform was given. Death occurred almost as soon as anæsthesia was produced. Dr. Kinlock enjoys a high reputation as a physician, and there is every reason to suppose that the anæsthetic was carefully given.

Interesting to Doctors.—The New York State Undertakers' Association was formed at Utica in 1880, and recently held its third annual convention at Rochester. A full report of this affair, as well as an account of the proceedings of the National Convention of Undertakers, held at Rochester at the same time, the delegates representing eighteen States, is printed in the *American Undertaker*, a weekly newspaper of handsome appearance, which

is published in this city. The same journal contains an article upon an interesting contest of skill that is to be held in New York during the summer. This will be nothing less important than an embalming match, in which the relative merits of various processes of preserving dead bodies are to be tested.

CHARCOT'S METHOD OF GIVING BROMIDES.—In an item in THE RECORD of July 1st, under this head, the doses were given in grains instead of grammes.

LEIDY MEMORIAL.—Several prominent Philadelphians are seeking to raise a testimonial fund of $100,000 for Dr. Joseph Leidy, of the University of Pennsylvania, designing that at his death it shall be applied to the maintenance of a Leidy Chair of Anatomy at the University.

LAVERAN'S MALARIA PARASITE has attracted the public attention, and called forth editorials in our daily press. The criticisms upon the alleged discovery by Dr. Corr should, therefore, be noticed. Dr. Corr expresses strong doubts as to the parasitic nature of these bodies which Laveran has considered to be the germ of malaria, and which he found in the blood of persons suffering from that disease. He (Corr) shows that the forms observed by Laveran occur only in the actual forms of malarial fever, in which Hayem has pointed out that the red corpuscles are diminished in number, and decomposition products appear in the blood, and is disposed to agree with Kelsch in considering Laveran's parasite to be merely pigmented corpuscles, due to retrograde metamorphosis.

CALCIUM SULPHIDE IN SMALL-POX.—Dr. R. H. Cowan, of Richmond, Va., writes: "Since reading in a recent number of THE RECORD a report read before the New York County Society on the use of calcium sulphide as an antisuppurative, the administration of this drug in small-pox has strongly suggested itself to my mind. As our means of combating this fearful disease are so limited, and the results of treatment so poor, it seems to me that calcium sulphide would be worthy a trial."

THE DANGER OF ADMINISTERING LARGE DOSES OF MORPHINE IN NEPHRITIC COLIC.—Dr. John A. McKennon, of Selma, Ala., sends us the following item: "Permit me to relate a case which to me was extremely interesting. On the night of March 15th I was called to see Mr. G. A——, suffering from nephritic colic. His history was that he had had several attacks, coming on about once in two months. His agony was so great that when I saw him first he was unable to remain in bed or room, but was walking on the roof of a two-story verandah (his room was on the third floor). On seeing his condition, I immediately gave him a hypodermic injection of morphia, one-fourth of a grain, put him in a hot bath, and gave him by inhalation (Squibb's) chloroform. After persisting in this course for half an hour, he begged me constantly for more morphine. I put him to bed and gave him one-fourth of a grain of morphine by mouth, and a warm hop poultice with some digitalis leaves over kidney where he complained of pain; his pain radiated down to penis, scrotum, and thigh, no relief being given after half an hour of this treatment (I would say here he was inhaling persistently the chloroform cautiously given). After twenty minutes more I gave one-sixth of a grain of morphia with one-fiftieth of a grain of atropia hypodermically. I was absent from the room about ten minutes, when I was summoned to come in haste from an adjoining room. To my astonishment and horror my patient was apparently dead — pulseless and gasping for breath, completely narcotized. After faithful work for about two hours, my patient recognized and spoke to me. You can imagine my relief. I will say here, when I left him with his friend and companion for the ten minutes, he was on the roof walking as I found him when first called. I can only account for this sudden transition in his case to the calculus passing out of the ureter into bladder. The sudden relief from pain caused the narcotics given to have the greatly increased effect. In resuscitating him, I found pressure, made heavily over the region of kidney and ureters, caused him to wince; this was the first evidence of returning vitality, and I think materially aided me in bringing back my patient to life, which was so near extinct. I write this to put the profession again on guard in the use of narcotics for the relief of great pain, especially when used hypodermically, when the pathological condition may subside so suddenly by natural processes."

PETROLEUM IN PHTHISIS. Dr. M. Milton, of Bradford, Pa., writes: "An article of mine, published in THE RECORD, May 13, 1882, on the use of petroleum mass in consumption, etc., has brought me many letters requesting my formula for petroleum pills. The following is my usual formula in phthisis:

℞. Petroleum mass ..... ʒ j.
Pulv. Cubeba,
Pulv. ipecac comp ..... aa ʒ ss.
Sulph. cinchonidia ..... ʒ j.

"Mix, make four-grain pills. Sig. one pill every three or four hours, or when the cough is troublesome. Also used in chronic bronchitis, asthma, catarrh, and all obscure lung troubles.

"The following ointment has never disappointed me in that troublesome of all diseases, pruritis ani:

℞. Petroleum mass,
Citrine ointment..... aa ss.
Bismuth subnitras..... grs. xxx.

"Apply locally, night and morning."

IRON IN CAPSULES.—Dr. A. W. Parsons, of Brainerd, Minn., writes: "I would like to suggest, for the possible benefit of some of your many readers, a method for administering tr. ferri chloridi, by which it does not corrode the teeth or prove a disagreeable dose for the patient. I have used it for some time, with none but the best results. When writing for the quantity of the tincture desired, write for a corresponding number of empty jujube capsules, and direct the patient to take one, fill it from the bottle, swallowing it with a drink of water. A Planten's No. 1 capsule will hold ten minims of fluid. There is no danger that the capsule will dissolve before it can be swallowed, as I have had them filled one day and taken the day following. Many other disagreeable tasting medicines might also be thus administered.

SCIENTIFIC PROGRESS.—According to Mexican journals, the President of the republic has ordered to be paid to Señorita Matilde P. Montayo a monthly pension of thirty dollars. This is to aid the young lady in pursuing the study of medicine, for which she has evinced great aptitude. She is studying at Puebla. We heartily applaud this sign of progress. —*Cronica Med.-Quir.*

Original Communications.

ON THE TREATMENT OF STRICTURE OF THE RECTUM.[1]

By CHARLES B. KELSEY, M.D.,

SURGEON TO ST. PAUL'S INFIRMARY FOR DISEASES OF THE RECTUM; CONSULTING SURGEON FOR DISEASES OF THE RECTUM TO THE HARLEM HOSPITAL AND DISPENSARY FOR WOMEN AND CHILDREN, ETC.

The treatment of stricture of the rectum is both constitutional and local, medicinal and operative. The first question to be considered is as to the advisability of anti-syphilitic treatment. In recent cases where syphilis is to be suspected, this should never be omitted. It is well to exercise great caution in this matter, however, and the cases in which the patient should be submitted to this form of treatment should be carefully selected. The practitioner who considers the majority of strictures as syphilitic, and indiscriminately uses mercury and iodide of potash, will be mistaken about as often as he who looks upon most of his cases as cancerous, and therefore incurable. The general condition of a patient with severe rectal disease is never up to normal, and an unnecessary course of medication will do harm rather than good.

Cicatricial tissue, though the result of specific disease, is beyond the reach of specific treatment; but where the case can be seen early enough, much may be gained by a thorough course of mixed treatment, and a gummatous deposit or a syphilitic sclerosis may be checked. Mercury and iodide of potash should both be given, and neither should be relied upon alone. Mercury in the form of ointment or oleate may also be administered by the rectum, and the full constitutional effect of the drug may be gained in a very short time by this method of administration. It is, however, an irritating application, and in cases of much ulceration and sensitiveness it may not be well borne.

There are various means by which the comfort of these sufferers may be greatly increased without recourse to operative treatment; and since in many cases the surgeon is limited to these means in his efforts to do good, it is well that they should receive careful attention. The most effectual of them all is a careful regulation of the diet, combined with rest, and with the administration of laxatives if occasion requires. The diet should be fluid and preferably milk. If milk is complained of soup may be substituted. A certain amount of farinaceous food may also be allowed, such as toast, crackers, and mush; but milk is the basis of the diet, and the other things are only intended to make that diet endurable. Many patients will assert from the outset that they cannot take milk, but nearly all can take it, and considerable quantities of it daily, for an indefinite period, if a little care is exercised in its administration.

The bowels should move once daily, and, if possible, without straining. Should any medication be necessary to secure this daily evacuation, it should be of the mildest kind. A little mineral water in the morning, a small quantity of rochelle salts or of the compound licorice powder, will answer every purpose. Where the opposite condition obtains, and the patient is troubled with diarrhœa and tenesmus, which result from the ulceration associated with the stricture, there is nothing better than bismuth and morphia—a good deal of the former combined with a very little of the latter. Purgatives are always contraindicated, because they cause straining and tenesmus, increase the conjestion and its consequences, and because, where obstruction exists or is threatening, they may do great harm by exciting a violent peristaltic action in an already weakened and ulcerated bowel.

Of rest as a therapeutic measure we have already spoken under the treatment of ulceration. The general strength of these patients is to be supported in every possible way; and in all of them, where it can be borne, cod liver oil will be found to answer a double purpose of tonic and laxative. When obstruction actually exists, much may be done in the way of general treatment before resorting to operation. Food should be almost absolutely suspended; opium should be given in large doses to allay the peristaltic action of the intestine, and large poultices covering the abdomen will be found to give great relief to the suffering. Dr. Norman Kerr has derived great benefit from the administration of the extract of belladonna in doses of one or two grains at short intervals in this condition; but the *rationale* of its operation is not understood. No purgatives should be administered, and the bowel should not be tapped with the aspirator. The dangers of this measure have already been pointed out.

By these means, combined possibly with gentle dilatation, the life of a patient may be prolonged in comfort. I have often been agreeably surprised at the happy results of such measures, where operative interference was either declined or contraindicated; and they can never be dispensed with though an operation be performed.

Dilatation.—This may be either gradual or sudden, partial or complete.

The use of bougies for gradual dilatation is an example of a good practice originating in false ideas. It was first practised with the idea of destroying the stricture by the action of medicinal substances applied in this way. Experience soon proved that simple bougies were not less efficacious than medicated ones, and the improvement was then supposed to be due merely to the mechanical stretching of the contraction. Instruments were therefore introduced as often, and allowed to remain in as long as possible—an idea in practice not yet entirely eradicated. But as Syme[1] pointed out, "it is the effusion of organizable matter in the cellular texture of the part which causes the stricture, and it is the absorption of this deposit that removes the disease. The bougie by its presence excites the action of absorption, and if the pressure be too great, too long continued, or too frequently repeated, there will be a great risk of causing more than sufficient irritation for the purpose, and of inducing again the very condition it is desired to counteract, the consequences of which must be a confirmation and increase of the disease."

The rules which should guide the surgeon in the treatment by gradual dilatation are now well understood and generally admitted. The dilatation should be intermittent and not constant. Attempts at constant dilatation, by means of bougies of any

[1] Advance sheets from the author's work on Diseases of the Rectum and Anus, to be published in Wood's Library of Standard Medical Authors for 1882.

[1] Diseases of the Rectum, p. 120. Edinburgh, 1838.

sort which shall remain permanently in place, generally result either in failure or actual disaster. They are not well borne by the patient, and when their use is persisted in, despite the protest which nature is pretty sure to make, the rectum becomes irritable, suffering is greatly increased, and there is decided risk of peritonitis and cellulitis.

The dilatation should never be forced. A bougie should be chosen which will readily pass the obstruction without stretching, and if there be any doubt in the operator's mind as to the proper size of the instrument, let one be selected which is too small rather than too large. An instrument should seldom be passed oftener than every alternate day, and once a week may be often enough. Little is gained by allowing it to rest for any length of time within the constriction.

Practised in this way much good may be done by this treatment. The patient may be greatly relieved and rendered very comfortable, but it must be continued indefinitely. For this reason, I suppose, it is not unfrequently used under false pretences in cases of hypothetical disease in hypochondriacal patients, and most of the reported cases of cure will be found reported by the laity. It has happened to me more than once not to be able to find any stricture after a patient had submitted to a long course of supposed dilatation, and there is but one way of convincing the patient under such circumstances. It consists simply in passing a full-sized instrument its whole length into the bowel.

This treatment by gradual dilatation, perhaps on account of the recent great advances which have been made in the treatment of stricture, has, to a certain extent, been superseded by more radical measures. It is not long since a well-written article on "Rectotomy" in one of our periodicals was begun by the statement that the treatment of stricture by dilatation was acknowledged to be a failure. This is by no means the case. The measure may not be curative, but it is perhaps as valuable a palliative as is at the command of the surgeon. It need not always be done with a bougie, for the patient's own finger, or that of a careful nurse, is often better than any instrument. It is applicable to all strictures, malignant or benign, which are within reach of the anus. When the disease is high up, it is not free from danger, and can scarcely be recommended on account of the uncertainty and difficulty of its application.

Divulsion.—The practice of forcible and sudden dilatation, or divulsion, is founded on entirely different principles, and is intended to overcome the constriction at a single sitting by means more or less violent. These consist of bougies of various kinds and sizes, generally made of metal; of dilators of many varieties and different degrees of power, or simply in tearing open the stricture with the fingers. More recently advantage has been taken of fluid pressure, and an instrument has been invented by Wales.

Of all the instruments for this purpose this is perhaps the best. There are now several cases on record where forcible dilatation with the fingers, either with or without previous nicking with a knife, has been followed by immediate relief to obstruction and fecal accumulation.[1]

This method has but few upholders, because it has been found to possess no advantages over more gradual dilatation, and to be in itself by no means devoid of danger. The dangers are hemorrhage, laceration and rupture of the bowel, peritonitis, and abscess. The relief obtained is not permanent, and the operation involves the subsequent use of gradual dilatation to preserve the calibre gained. Even when applied to the lower three inches of the bowel, the operation is rough, uncertain, and unsurgical; and above this point it is scarcely admissible. Nevertheless it has occasionally served a good purpose, and a few happy results are recorded in cases of linear contraction.

Division of the stricture.—The practice of nicking a linear stricture in two or three places as a first step in the treatment by dilatation is a good one, and generally devoid of danger. It can usually be done entirely by the sense of touch with a straight, blunt-pointed bistoury passed along the left index finger as a guide.

The operation of internal proctotomy consists in dividing the whole of the stricture tissue, in the median line, either anteriorly or posteriorly. It is called internal because the incision is confined within the rectum and does not involve the sphincter; and it is generally performed with a knife in preference to the cautery or écraseur. Regarding this operation there is not very much which needs to be said. There have been many unpublished cases of its performance, especially in New York, and I should probably express the general feeling of the profession fairly well were I to say that it is not looked upon with any very great favor. Though at first sight it might appear a less serious operation than the external one next to be described, it is in reality attended by greater danger. The sphincter being still undivided prevents a free discharge from the wound, and in this way greatly increases the liability to pelvic inflammation. The danger of hemorrhage is not very great when the incision is confined to the median line, but should there be trouble from this cause, the advantage of a free external wound in controlling it at once becomes manifest. When the cut is anterior as well as posterior, the anatomical relations must be borne in mind lest the peritoneum in the female or the bladder in the male be wounded. The following case represents my entire experience with the operation, which I abandoned after once trying, being convinced of the advantages of the operation next to be described.

Case I.—Mrs. ——, aged twenty-six. This patient was a woman with a syphilitic history. The stricture was of eight years' growth, and had previously been treated both by nicking and by gradual dilatation. As a result of this treatment she describes an attack of "inflammation of the bowels," which made her very dangerously sick. The stricture was two and one-half inches from the anus, was of just sufficient calibre to engage the end of the index finger, and did not involve more than one inch of the bowel, though there was the usual amount of ulceration above it. I divided the constriction by a single deep, posterior incision which did not implicate the sphincter, and the operation was followed by an attack of pelvic peritonitis which nearly cost the patient her life. This may have been due to the operation, or it may have been due to attempts at dilatation which were begun early and followed with perhaps too great vigor; but it was certainly excited by the patient leaving her bed, going down-stairs, indulging freely in wine, and submitting to the embraces of her lover.

Three months after the operation I completely

[1] Smith: Diseases of the Rectum. Louisville Medical Herald.

lost track of the case. At that time the calibre of the stricture was so much increased as to permit of easy digital examination of the parts above. The increased size seemed due entirely to a deficiency in the old cicatricial tissue at the point of incision, the rest of the circumference of the part having much the same feel as before the operation. The act of defecation was much less painful, and her condition was altogether much better. I never counted the case as showing what could be done by the operation until a few months ago and more than four years after its performance. In fact I had little doubt that the contraction had returned, and supposed the patient had either succumbed to the disease or submitted to colotomy. At that time the woman was in perfect health and spirits, and since then I have thought better of the operation.

Other similar cases have been reported in this country with equally good results.[1]

External proctotomy involves not only the division of the stricture but of all the parts below, including the anus. This is the operation which is usually accredited to Nélaton. It may be performed in several ways and with the knife, galvano-cautery, or écraseur. The operations with the galvano-cautery apparatus and the écraseur were invented by Verneuil,[2] and have been practised by him more than by any other surgeon.

The operation as performed by him consists in passing the left index finger through the stricture for a guide, and then plunging a trocar from a point in the median line just in front of the tip of the coccyx into the rectum onto the tip of the finger above the stricture. After drawing out the trocar a fine bougie is passed through the canula into the rectum and brought out at the anus. Removing the canula the bougie is replaced by the chain of the écraseur and the operation is completed.

The same section may be accomplished by repeated strokes with the galvano-cautery or thermo-cautery-knife. Both operations are intended to prevent hemorrhage. By any one of these methods all of the stricture tissue and the parts below may be divided. Nélaton's method was to introduce the left index finger as far as the stricture, and with this as a guide, to pass in a blunt bistoury and divide all the soft parts below the stricture as nearly as possible in the median line. By pulling open the lips of this incision the stricture comes plainly into view and may be divided by a second incision.

In performing the operation, I prefer the knife to any other method of cutting, and have had one adapted for the purpose, which is shown in the figure.

It is simply the lithotomy-knife, made heavier in the back and at the handle, for with an ordinary bistoury there is great risk of a bad accident from breaking the blade in cutting through an old stricture, which is often as hard as cartilage. The blunt point on the end of this blade is a great convenience in passing the knife along the index finger, avoiding, as it does, all chance of wounding the operator.

The best position for the patient is the lithotomy position, and the incision with the knife figured may be made at one stroke. The blade should be passed fairly through the stricture before the cutting is begun, then the stricture is divided completely, as near as possible in the median line posteriorly, and, finally, the incision is continued downward and outward, growing deeper as it approaches the perineum, till finally all the soft parts are severed between the anus and the tip of the coccyx. In this way a large triangular wound is made, the apex being within the rectum above the stricture and the base at the skin, and all the stricture tissue is completely cut through. There will generally be a free gush of blood when the cut is made; but I have never seen so much as to make me prefer the écraseur or cautery operation to the knife. The rectum should at once be packed in the manner already described, without waiting to try any other method of stopping the bleeding. This is a precaution which should never be omitted.

It may be asked, why should so large an incision be made and so much tissue be divided below the actual disease? The answer is simple. In the first place, this incision provides for free drainage and discharge in the most effectual of all ways, by furnishing a dependent gutter-shaped opening which cannot be closed. This is better than any number of drainage-tubes; and it is this alone which makes the external operation a safer one than the apparently slighter internal incision.

In the second place, by this incision the sphincter is completely divided and another great point is gained. The operation we are now considering, it should be remembered, is nothing less than a substitute for colotomy in the same class of severe cases for which that operation is generally considered the only relief. One point which is exceedingly well brought out in the study of these cases, is the important part played by the sphincter muscle in the sufferings accompanying severe cases of stricture and ulceration, and the relief which may be obtained by its simple division without interference with the stricture itself. In one case of Verneuil's, for example, there was a stricture high up, and yet, under a mistaken diagnosis of spasmodic stricture at the anus, the sphincter was cut through with the galvano-cautery, while the real cause of the trouble was untouched, and yet there was entire relief from suffering. The same experience has been repeated often enough to establish the general principle that free division of the sphincter is not only a justifiable therapeutic measure for the relief of the pain attendant upon either malignant or benign stricture or ulceration, but is often the best means at the surgeon's hand for allaying the suffering.

By the external operation, then, the obstruction is divided and one great cause of suffering is abolished, and both are effected by the same incision.

The after-treatment of the incision is very simple. When the rectum has been tightly packed with picked lint, it will usually cause more or less uneasiness on the following day, unless the patient be kept partially narcotized. For this reason I generally remove enough of it on the following day to give the patient ease, and the remainder is allowed to remain until suppuration has commenced. It may usually all be picked out by the third or fourth

[1] Whitehead reports an old fibrous stricture in which he made both an anterior and a posterior incision, and continued the treatment by dilatation. Two months after the operation the patient was much improved, and the passages were large and natural. Amer. Jour. Med. Sci., January, 1871. Lente and Beano each report a similar case in the same journal, the former in July, 1873; the latter, April, 1873.

[2] Verneuil: Des rétrécissements de la partie inférieure du rectum, et de leur traitement curatif ou palliatif par la rectotomie linéaire, ou section longitudinale de l'intestin, a l'aide de l'écraseur. Gaz. des Hôp., October 26, 29; November 7, 9, 16, 19, 1872. Also, Traitement palliatif du cancer du rectum au moyen de la rectotomie linéaire.—Gaz. Hebdom., March 27, 1874.

day without causing any pain. The subsequent treatment of the incision itself consists wholly in cleanliness, which may be obtained by gently syringing the part with warm water and a little carbolic acid. No particular attention need be given to regulating the passages. The first one after the operation will often be the only comfortable one the patient has experienced for years; and unless there is some special reason for regulating their frequency or quality, they may be left entirely to nature.

The case which follows will give a very fair idea of what may be hoped for from this method of treatment.

CASE II.—Mrs. ——, aged thirty-five, mother of one child, twelve years old. This patient had always suffered from obstinate constipation, and several years ago was relieved artificially of impacted fæces. Her husband assures me there is no venereal history, nor is there the slightest reason to suspect any. The symptoms of rectal trouble began six years after marriage, at which time she was operated upon for internal hæmorrhoids. Soon after this she began to suffer from the usual symptoms of ulceration of the rectum.

The examination revealed advanced ulceration of the whole circumference of the bowel, with stricture about an inch and a half from the anus, which just admitted the end of the index finger. In connection with the stricture there were two fistulæ. For this condition the patient had submitted to the usual treatment by dilatation, but without relief. Her general condition was such as is usually seen in advanced cases of this disease. She had lost flesh and appetite, and the suffering was extreme. What she most dreaded was an action of the bowels, so great was the pain attendant upon it.

The operation which I have described was performed. One of the fistulæ was also divided, but the other, which communicated with both rectum and vagina, was left to the chance of spontaneous cure, since the usual operation for recto-vaginal fistula would have been necessary for its closure. The ulcerated surfaces, both above and below the stricture, which were of large extent, were scraped with the handle of a scalpel to try and excite a healthy action, and the wound was thoroughly packed with lint.

The subsequent treatment consisted in absolute rest in bed, milk diet, and dressing the wound by the introduction of a pledget of lint. After a few days a painless evacuation occurred from the bowels, and these continued regularly. No attempt was made at passing a bougie, and the stricture was left entirely to itself. The immediate effect of the operation was a most marked and satisfactory relief of the most painful symptoms.

The passages were painless and involuntary, but always preceded by the warning sensation which gave the patient ample time to prepare herself. At the end of six weeks she had improved greatly in general condition and was more comfortable than at any time since the trouble first began. She had regained the control of her evacuations, which were normal and occurred daily without pain; but there was incontinence of wind. In this condition the patient returned to her home in the West under the care of her own physician.

Six months later she again came to New York for treatment. There had been no return of the suffering and the general health was greatly improved; but there was still considerable discharge of matter from the anus, and she was uneasy about the occasional involuntary discharge of flatus. Except for these two things she would have considered herself well. An examination showed a very marked decrease in the amount of the stricture tissue and a softening of the induration. The incision through the soft parts below the stricture had never healed, the patient having exercised freely and constantly while at home, and a good deal of the discharge complained of came from this cut surface. There were two distinct lines of ulceration within the rectum; one on the anterior wall, superficial, about half an inch broad and an inch and a half long; the other at the site of the incision, posteriorly, deeper, and running a considerable distance up the bowel. At all other parts the old ulceration was entirely healed and its former location was marked by a thin, glistening, bluish-white cicatrix.

Attention was at once turned toward the healing of these ulcerated surfaces. The patient was put upon an almost absolute milk diet, and after a time was confined absolutely to bed. The remains of the primary incision in the perineum were induced to heal by daily dressings of lint and balsam of Peru, and the ulceration above was treated by applications of bismuth and opium, nitrate of silver, balsam of Peru, iodoform, and oxide of zinc, alone and in combination. At the end of two months she was so nearly well that attention was turned to the recto-vesical fistula. The openings into both rectum and vagina were small, but there was a considerable abscess cavity in the recto-vaginal septum, which discharged through both openings. This cavity was freely laid open into the rectum to allow of drainage. After one month more the ulceration on the anterior wall of the rectum had entirely healed, that on the posterior wall, which was much more extensive, had nearly healed; the incision had cicatrized, and the abscess cavity in the recto-vaginal wall had closed, leaving only an exceedingly small fistulous track communicating with the rectum and the mouth of the vagina, but causing no symptoms. The discharge from the rectum had practically ceased, and in this condition, which certainly warranted a prognosis of speedy and complete recovery, she again returned to her own physician to continue the treatment for a few weeks longer till she should be entirely well. Two months later I again heard from her and the report was most favorable.

This case is certainly worthy of a careful consideration. When the lady applied to me all the supposed resources of rectal surgery had been exhausted except colotomy. I do not think I exaggerate when I say that most surgeons would have at once decided in favor of colotomy, and would have been justified, of course, in so deciding; for colotomy is still the recognized mode of treatment in these cases. In my own mind, colotomy was always present as the *dernier ressort;* but having tried proctotomy in several instances, and been more or less satisfied with its results, I determined to make this a test case. The result was most happy, and yet there is nothing exceptional in that result, though the great tractability of the sufferer and her determination to do all that was asked of her, alone rendered it possible. She is now infinitely better off than she would be with an artificial anus. In an analysis of cases made some time since I found that in eighteen cases of non-malignant stricture treated in this way all the patients were greatly relieved as to general health or local condition, or both. In eight, kept under observation for a period of from

three months in one case to four years in three cases, the cure was absolute, there being no return of the contraction, and in some a disappearance of all induration. A tendency to recontraction is noticed in four, due in two cases to the fact that all of the stricture was not divided.[1]

I have performed this operation in various other cases and have every reason to be satisfied with it. In malignant or non-malignant stricture and ulceration I have never seen it fail to give immediate relief to suffering, and as a means of relieving the pain of this disease I believe it to be fully equal to colotomy. It fulfills, also, the other great indication for colotomy—the overcoming of obstruction. Too much must not be expected of the operation, however. I have seen several cases in which I have advised the operation in the practice of others which have led to disappointment for this very reason. An old stricture of the rectum, with extensive ulcerations, is a well-nigh incurable disease. Proctotomy may be certainly relied upon to accomplish two things —the relief of pain and the overcoming of obstruction—even in the worst cases, and in favorable cases taken in time it may effect a cure, but it will not cure them all. Nothing will. After proctotomy, as after colotomy, there is still a diseased rectum, which must be treated by every possible means. In the case given above I succeeded ultimately, by long and patient efforts, in curing that; but it cannot be done in every case. The stricture is easier to overcome than the ulceration which accompanies it; and after the former is divided the latter still remains and must be treated as an ulcer with the same results, both good and bad, as usually attend the treatment of that most painful, obstinate, and often incurable condition. But the chances of curing it, and, at all events, of relieving it, are much better after this operation than before.

It is understood that I do not advocate this operation in cases of disease high up the bowel, though it may be done at a considerable distance from the anus, and where an incision involving the anterior wall would be unjustifiable, for the anatomical reason that the peritoneum extends so much lower in front than behind.[2]

Colotomy.—This is the last resort of surgery in dealing with ulceration or stricture of the rectum. In ulceration it may be a curative measure; in stricture it is only palliative, and should, therefore, not be undertaken till all other measures have failed. It fulfills two important indications: the relief of pain and the overcoming of obstruction, and we have already seen how both of these may be met, in many cases, by other means, which, even were they only partially successful, are infinitely preferable.

When none of the methods already pointed out serve to assuage the suffering, and when it is probable that the pain is not due to an irritable sphincter muscle, or to pressure on neighboring nerves from the mass of the deposit, cancerous or otherwise, in which latter case colotomy cannot be expected to afford any relief, and when none of the means already described for preventing or overcoming obstruction can be applied, colotomy may be resorted to. There is, however, but one class of cases in which obstruction may not be overcome by attacking the stricture itself instead of the bowel above it, and that is where the stricture is so high up that it cannot be safely reached by the knife to cut it.

Judged by these rules, colotomy would be limited to a small proportion of cases. It would be tried after division of the sphincter and of the stricture, had each failed to give relief in disease near the anus, and practically would be limited to disease high up the bowel. Such restrictions would greatly diminish the number of operations of colotomy, especially in the United States, and it is possible that this might be done with advantage. We seldom see in the reports of the operation, in current literature, any other reason given for its performance than the existence of obstructive or painful disease, as though the mere presence of a stricture of the rectum, malignant or benign, were a justifiable reason for at once resorting to this repulsive and serious operation.

It has yet to be proved that colotomy delays cancerous growth, but it certainly prolongs life by diminishing pain and relieving obstruction; though the relief to the pain may be, and often is, only partial, for a very small amount of fæces which has passed the artificial anus, may cause as much suffering and tenesmus as the natural quantity.

In almost direct proportion as the operations of proctotomy and of partial or complete excision of strictures have become popularized, and their advantages in suitable cases have become manifest, the operation of colotomy has been limited, and the natural objections to it, both by patient and surgeon, have been allowed more weight in influencing the treatment. Especially is this the case in France, the birth-place of the operation, and in Germany, while England, as represented by Allingham, is plainly following in the same course. In this country alone does colotomy still hold its sway, partly, I cannot help believe, for the reason that its various substitutes have never been so thoroughly tried here as on the other side of the water.

TREATMENT OF YELLOW FEVER BY PHENIC ACID.—M. Lecaille, of Rio Janeiro, following out the doctrine of ferments, has been treating yellow fever with phenic acid. In twelve cases under his care, success was complete. In one instance the stage of "black vomit," etc., had set in, and the patient was almost moribund. Lecaille saw him at this time, *i.e.*, the fifth day. Phenic acid was injected hypodermically, syrup of the phenate of ammonium was given per orem, and sulpho-phenic per rectum. This was done at intervals of two hours. On the third day of treatment the patient was pronounced cured. A second patient was in the cosmic stage of the parasite. Ten hypodermics, together with rectal injections of sulpho-phenic and glyco-phenic were made, with the result of bringing about a cure on the seventh day.—*Cronica Med.-Quir.*

CASES OF ACUTE GLAUCOMA,

IN THE PRACTICE OF DR. C. R. AGNEW AND DR. DAVID WEBSTER.

(Reported by DR. WEBSTER.)

CASE I.—Mrs. C. C——, aged thirty-five, was referred to Dr. Agnew by Dr. George D. Bleything, April 13, 1882. She said that about the middle of last February she was attacked with a severe inflammation around the stump of a decayed and broken off eye-tooth, that of the left upper jaw. The gums were so swollen that she could scarcely open her mouth, and she had severe pain through the left side of her face and head. This condition of things continued for nearly two weeks, and was beginning to improve when she was suddenly attacked with a severe supraorbital neuralgia of the *right* side. After this pain had lasted four hours she "felt a sudden snap in the right eye," as though something had given way, and the sight became instantly obscured. The eye was bloodshot for three or four days, and then the sight cleared up gradually till she could see objects in the room, or the pattern on a carpet. There had been little pain in the eye since the first few days, but some occasionally over the eyebrow.

Present condition.—Eyeball slightly injected, pupil widely dilated, iris pressed forward, cornea steamy, optic disk cupped, but finer details of fundus visible. Tension + 2. V. = $\frac{2}{200}$. Ordered eserine, two grains to one ounce, one drop in the eye three times a day.

April 15th.—V. = $\frac{1\frac{1}{2}}{200}$. Pupil does not yield to eserine.

The use of eserine was continued until April 20th, when, as the eye failed to show any improvement, the patient was placed under ether, and an iridectomy was performed by Dr. Agnew. Only the eye operated upon was bandaged, the other being left open in order to avoid one of the supposed agencies in the causation of acute glaucoma in the second eye after an operation upon the first. The eye healed kindly after the operation, and the patient was allowed to go home on the eighth day with V. = $\frac{2}{200}$. The left eye was unaffected throughout.

May 15th.—No pain since the operation. The redness of the eyeball and the opacity of the media have disappeared. The optic disk is deeply excavated, and there is a retinal opacity about a quarter as large as the disk in the supero-temporal quadrant. V. = $\frac{1\frac{1}{2}}{200}$; field limited. Tension normal.

It seems most probable that glaucoma simplex existed in this eye previously to the maxillary periostitis, and that the latter caused an acute glaucoma to supervene through the agency of reflex irritation of the fifth nerve. It is quite possible, however, that the excavation of the optic disk was produced by the continued high degree of intraocular pressure, which lasted for six weeks.

CASE II.—Mr. M——, aged seventy-two, bachelor, cotton broker, was first seen by Dr. Webster on February 22, 1877. He stated that he had been totally deaf since he was thirty years old, and had never learned the art of communication by signs, but had always to be written to, while he carried on his part of the conversation *viva voce*. A week before we saw him, Mr. M. had caught cold in his head. On Friday (16th) his eyes watered and "bothered" him in the office. On Saturday (17th) he went out without his overcoat, and thus added to his cold. On Sunday (18th) his eyes became red and painful, and his sight failed rapidly, and on Monday (19th) he was blind in both eyes all day. He could be only imperfectly communicated with by the sense of touch, and he passed the day in a very wretched condition, groaning with pain in his eyes, but forbidding his friends to summon a physician, in the expectation that his trouble would soon pass away. On Tuesday morning (20th), the sight had returned to the right eye in some degree, and has since gradually improved so that now (22d) he reads coarse writing, and with + $\frac{1}{4}$ has vision = $\frac{20}{30}$.

Left eye.—V. = perception of light; pupil dilated and fixed; iris pressed forward, eyeball injected, and media so turbid that fundus cannot be observed. Tension increased (+2). Still a dull pain behind left eye, but none in right. Lids of both eyes somewhat red and swollen, but left more so.

February 23d.—Iridectomy upon left eye in the morning before breakfast, by Dr. Agnew. A retentive bandage was placed over the eye operated upon, the other being left open as his only means of communicating with the external world.

March 7th.—R. V. = $\frac{20}{30}$ with + $\frac{1}{4}$. L. V. = $\frac{20}{40}$ with + $\frac{1}{20}$. No cupping of optic disks. Tension normal in both. There has been no pain since the operation. The eye improved steadily, and Mr. M—— was able to return to his office on the thirteenth day after the operation.

We heard only favorable accounts of Mr. M—— for nearly two years. On January 23, 1879, he came to consult us again. He had had some pain in and about his right eye for several weeks, and the vision of that eye was now reduced to perception of light. Ophthalmoscopic examination showed slight central cloudiness of the lens and an excavated optic disk, but the details of the fundus could not be made out. The pupil was sluggish, but not notably enlarged; the anterior chamber was shallow, but the tension was very slightly, if at all, increased. An iridectomy was thought advisable for the relief of pain, and with the hope of some improvement in sight.

Two days later (January 25th) ether was administered, and an iridectomy upward was performed by Dr. Agnew. Only the eye operated upon was bandaged, the other eye being left open as before for the patient to read writing with. The eye recovered without pain or unpleasant reaction, and Mr. M—— was soon at his work again.

Our last record of this patient's visits to our office was on November 7, 1881, when the following note was made: "R. V. = perception of light. L. V. = $\frac{20}{200}$. Still reads coarse writing." He died May 5, 1882.

There are some interesting points in connection with Mr. M.'s case. In the first place, it was unfortunate for him that both his eyes were not operated upon early in the first attack. If this had been done, the chances are that he would have retained useful sight in both as long as he lived.

In the second place, we think it remarkable that his right eye recovered vision of $\frac{20}{30}$ without treatment, after having been "blind" for all one day.

His management after the operation was necessarily somewhat extraordinary. His room was darkened, and he was told to lie still and to keep the unbandaged eye shut. But it was necessary for him from the first to put on his spectacles and read messages several times daily. When visited the day after the first operation he was found sitting up in bed and smoking a cigar. Yet, notwithstanding the difficulties in the way of his successful management, his recovery after both operations was quite

as rapid as is usual in cases where the greatest care is observed.

Case III.—Miss A. B——, aged sixty, very deaf, was as well as ever Tuesday night (May 30, 1877) when she went to the theatre. On her way she was attacked with a fit of sneezing which made her think she had caught cold. Soon after entering the theatre she had a copious watery discharge from her right nostril. After she had watched the play about two hours the light began to dazzle her eyes, the lids of the right eye began to swell, and she very soon noticed that on closing her left eye she could see very little with the right. The eye immediately became very painful. The pain has continued day and night ever since, and she now (June 1st) keeps up a constant groaning. She keeps the eye closed, partly on account of the swelling of the lids, and partly because of its sensitiveness to light.

Inspection shows a moderate amount of chemosis. The pupil is dilated to about three times the size of its fellow, and the anterior chamber is shallow. The tension is much increased (+ 3). Vision, fingers at three feet. The cornea is cloudy, and there seems to be a haziness of the media back of the cornea. A slightly reddish reflex is all that can be seen of the fundus.

June 2d.—A broad, peripheral iridectomy upward, under ether, was performed in the morning before breakfast by Dr. Agnew. Charpie with a flannel bandage and a black silk mask were applied over both eyes.

Upon coming out of the ether the patient found that the pain was gone. The eye gradually recovered until on the 13th she was able to come to the office. Her vision was then R., $\frac{10}{70}$; L., $\frac{20}{70}$.

June 18th.—R. V.= $\frac{20}{15}$.

June 26th.—R. V. = $\frac{20}{60}$ with — $\frac{1}{12}$s. ⌒ — $\frac{1}{60}$c. ax. 90°. L. V. = $\frac{20}{30}$ with + $\frac{1}{12}$s. ⌒ + $\frac{1}{60}$c. ax. 180°.

There was at this date no redness of either eye, and both visual fields were normal.

Case IV.—March 8, 1875.—Miss M. J. K——, aged sixty, says that her eyes have been weak for years. When she tried to do work requiring fixed attention, as in crocheting, her left eye would give out, and her sight would be "quickened" by any change of work, even to reading. She has had periods of very foggy sight, followed by clearer vision. She had much pain in the left eye a fortnight ago, but very little since. R. V. = $\frac{20}{20}$ with + $\frac{1}{1}$. Visual field normal.

Left eye, vision, only perception of light for the last two weeks. Tension much increased (+ 2); pupil enlarged and sluggish; ciliary region injected; cornea hazy. Fundus not to be seen.

March 9th.—Ether administered, and an iridectomy upward performed by Dr. Agnew.

March 12th.—Eye not inflamed or painful, but sight not improving.

April 1st.—Left eye, vision = $\frac{20}{200}$ with + $\frac{1}{10}$. Ordered + $\frac{1}{10}$ delicately tinted blue for both eyes, for constant use.

August 18th.—V. = $\frac{20}{15}$ each eye, with her glasses (+ $\frac{1}{10}$).

The result in this case was good beyond expectation. We do not often see eyes with the sight reduced to perception of light for two weeks by acute glaucoma recover vision of $\frac{20}{20}$ after an iridectomy.

Case V.—December 3, 1874.—Mrs. E——, aged forty-nine, during the past few years has had very severe headaches, occurring sometimes as often as once in two or three weeks, and compelling her to go to bed. She has had for a year occasional chromopsies, and during the past six months occasional spells of transient smoky sight. On Thanksgiving day she drove out, and was exposed to a cold wind, went to bed very tired, and after midnight began to feel restless and somewhat nauseated. Pain came on in the head, centering in the left eye. On Friday the headache continued, and the left eye began to close. On Saturday vision was observed to be very defective in the left eye, so much so that she could only see the position of the window. The eye continued closed, painful, and discharging scalding tears until Tuesday afternoon, when Dr. Agnew was called in to see her. Examination revealed all the physical signs of glaucoma in the left eye. Tension increased (+ 3); pupil dilated and fixed; pupillary field hazy, rendering the fundus invisible; ciliary vessels injected; slight subconjunctival œdema; vision reduced to counting fingers at five feet.

Right eye, tension + 1; pupil sluggish and superotemporal segment a little dilated; media clear; no cupping of disk; no pulsation of retinal vessels. Reads ordinary type at 18″; visual field normal.

Advised immediate iridectomy upon left eye. Case seen by Dr. Knapp, who concurred in diagnosis and advice.

The patient was put under ether, and an upward iridectomy was performed on the left eye by Dr. Agnew. There was some bleeding into the pupil from the cut iris.

December 21st.—The eye recovered kindly from the operation, and the media have cleared up.

R. V. = $\frac{20}{15}$ with — $\frac{1}{36}$ c. ax. 90°. L. V. = $\frac{20}{40}$ with — $\frac{1}{36}$ c. ax. 90°. Right visual field at one foot, 21″ vertically and 29″ horizontally. Left visual field larger than right in all directions.

Examination of the right eye with the ophthalmoscope shows a very slight haziness of the media, and an apparent multiplication of enlarged bloodvessels converging to the optic disk.

The eye shows slight increase of tension, the pupil is sluggish and slightly dilated in its superotemporal portion, and there is slight engorgement of two or three veins emerging from the superonasal ciliary region.

There is no excavation of either optic disk, and no pulsation of the retinal vessels.

January 19, 1875.—Vision the same in both eyes as at last examination. Tension normal in both. No smoky vision since last date.

April 10th.—Vision = $\frac{20}{30}$, each eye, with — $\frac{1}{30}$ c. ax. 90°. Ordered the same, very large, and delicately tinted blue.

November 3d.—Eyes continue the same.

October 17, 1878.—R. V.= $\frac{20}{15}$ with — $\frac{1}{36}$ c. ax. 90°. L. V.= $\frac{20}{30}$ with — $\frac{1}{36}$ c. ax. 90°.

January 8, 1879.—R. V. = $\frac{20}{15}$ with — $\frac{1}{36}$ c. ax. 90°. L. V.= $\frac{20}{70}$ with — $\frac{1}{72}$s. ⌒ — $\frac{1}{36}$c. ax. 90°.

July 14th.—In the latter part of June the *right eye* ached, and the sight was somewhat obscured. Vision was reduced to $\frac{20}{60}$, but under the use of pilocarpine eye drops and laxative doses of podophyllin went up to $\frac{20}{30}$. She has been kept awake nights for hours at a time by the aching. Vision = $\frac{20}{15}$ each with her glasses.

Ophthalmoscopic examination shows commencing excavation of right disk. Visual field and tension normal. Advised to wear her concave cylindrics constantly for distant vision.

September 4th.—Was very comfortable until two weeks ago. One night last week she awoke, and, after lying awake for half an hour, the right eye began to be painful. She had a drop of pilocarpine

put in, which relieved the pain, and she went to sleep again. There has been some pain in the eye every evening since, at about twilight, but a drop of the pilocarpine solution has produced prompt relief. The eye has not been red at any time. Vision = $\frac{20}{20}$ each with her glasses. There is decidedly increased cupping of the disk of the right eye. There has been no trouble with the left since the operation.

September 24th.—V. = $\frac{20}{20}$ each. Has obscurations and pain in right eye almost every day. The excavation is decidedly more marked, but the visual field remains normal.

October 7th.—Has been pretty comfortable most of the time since last visit.

A week ago, at tea-time, she had an attack of pain and obscuration of vision of right eye, lasting about twenty minutes. Has occasionally been kept awake by pain for an hour at a time, but always relieved by pilocarpine; V. = $\frac{20}{20}$ each.

January 24, 1880.—V. = $\frac{20}{20}$ each with her glasses. Visual field of right eye contracted on all sides, but the temporal. Excavation of optic disk m. $\frac{1}{10}$. No cupping of left disk. Since last visit she has had more frequent attacks of obscuration of vision of right eye. At times could not distinguish objects with it.

January 28th.—Patient put under ether, and an iridectomy upward performed upon the right eye by Dr. Agnew.

February 28th.—No unpleasant reaction followed the operation. Atropine was dropped into the eye only once to insure the non-formation of adhesions of iris. There has been no pain or obscuration since. R. V. = $\frac{20}{20}$ with $-\frac{1}{30}$ c. ax. 90° ⌒ $-\frac{1}{48}$ c. ax. 180°.

There has been no return of glaucomatous symptoms in either eye up to the present time, May, 1882.

Case VI.—November 7, 1874.—Mrs. D. A. M——, aged fifty-five, was attacked with neuralgia of left brow a year ago, and has suffered from such attacks frequently since. Three weeks ago she "caught cold in her left eye." It was red and very painful for more than two weeks. There is now much less redness and no pain. The tension is much increased (+3); the pupil is dilated and fixed, and presents that peculiar *greenish* reflex from which the disease takes its name. Vision = $\frac{3}{200}$.

Right eye, vision = $\frac{20}{40}$ with + $\frac{1}{48}$, visual field slightly limited supero-nasally. Tension normal.

Examined with the ophthalmoscope, the fundus and optic disk of the right eye, were found to be slightly congested. There was no excavation of the papilla, and no want of transparency of the media. It was impossible to see anything more than a dull reddish reflex from the fundus of the left eye.

An immediate iridectomy was advised, but for reasons, on the part of the patient, was not done until ten days later (November 17th), when she was put under ether and the operation was performed by Dr. Agnew. There was bleeding into the pupil.

December 3d.—The eye recovered from the operation without any excessive reaction. V. = $\frac{15}{200}$.

December 8th.—The right pupil is a little larger than normal, and somewhat sluggish. The upper half of the disk is very red.

R. V. = $\frac{20}{30}$ with + $\frac{1}{48}$s. ⌒ + $\frac{1}{48}$c. ax. 90°. L. V. = $\frac{15}{200}$; no improvement with glasses.

December 26, 1876.—A little over two years after the operation upon her left eye, Mrs. M—— presented herself with acute glaucoma of the right eye. Iridectomy was immediately performed by Dr. Agnew upon this eye at the Manhattan Eye and Ear Hospital, and the recovery was good, but unfortunately the resulting vision was not noted.

Case VII.—July 8, 1873.—T. D. S——, aged fifty-five, barber, says that Dr. Agnew performed an iridectomy upon his *right* eye four years ago for the relief of acute glaucoma, he having suffered for several months from "terrible neuralgia" in and about the eye.

Another attack of circum-orbital neuralgia of the *left* side came on two weeks ago, and lasted until three days ago. He still sees rings round the lights, and complains of impaired vision.

The left eyeball is injected and its tension above the normal.

R. V. = $\frac{20}{30}$ with + $\frac{1}{7}$. L. V. = $\frac{20}{100}$ with + $\frac{1}{7}$.

The right visual field is of normal extent downward, but extends upward and laterally from the point of fixation only about two inches.

The left visual field is normal downward, extends upward six inches, temporally nine inches, and nasally seventeen inches. Both visual fields were measured at a distance of one foot.

Ophthalmoscopic examination revealed the same conditions in both eyes, viz., general fundus H. $\frac{1}{7}$, and disk E., showing an excavation 1.63 mm. in depth.

An immediate operation upon the left eye was advised, but the patient postponed it until July 14th, when he had another acute exacerbation, with great pain and increase of tension, with a corresponding impairment of vision.

Dr. Agnew then performed an upward iridectomy upon the left eye.

August 1st.—The recovery has been without complication.

L. V. = $\frac{20}{40}$ with + $\frac{1}{10}$s. ⌒ + $\frac{1}{24}$c.

December 24th.—Both eyes have remained quiet. The vision and refraction are the same as at last visit, and the patient has resumed work.

Case VIII.—August 31, 1876.—Mr. W——, aged fifty-five, married, had noticed for six months that his spectacles were unsatisfactory, and had experienced occasional photopsiæ. He had observed a tendency to blurring in near and distant vision, coming on without any other provocation than ordinary use. He had suffered from decayed teeth, and had had considerable work done by a dentist during the same period. On Tuesday (12th) he took a drive in the country to the top of a hill, and was exposed to a cold wind while looking at the prospect. That night an active inflammation at the roots of the left upper incisors set in, and a swelling of the most painful character extended over the front of the superior maxillary bone through the soft parts, with some swelling of the evelids of the same side. The same day, or the day after, the vision of the left eye became affected. The degree of pain in the eye itself was masked by the extreme pain throughout the whole of that side of the face, but he remembers that the application of warm poultices to the face sent darting pains into his left eye.

Status præsens.—Inflammation over the alveolus subsiding; left eye counts fingers at three feet; cornea slightly hazy; ciliary region deeply injected; pupil moderately dilated and immovable; anterior chamber diminished in depth; media so hazy as to make it impossible to see the details of the fundus; tension increased. Myosis of pupil of right eye; patient too nervous to permit its vision to be accurately tested.

September 2d.—Iridectomy upward on left eye by Dr. Agnew. No vomiting from the ether.

September 7th.—Eye did well until last night when patient suffered much from periorbital pain. Applied two leeches to temple.

September 9th.—Pain came on again last night. This morning the dentist removed the pulp of an aching tooth, and two leeches were applied to the temple in the afternoon.

September 14th.—Patient has had more or less pain every night until now. To-day the dentist *extracted* the painful incisor, and *broke off* the troublesome eye-tooth.

September 19th.—Both the eye and the face have steadily improved since the last date, and the patient is now able to go about.

R. V. = $\frac{20}{100}$: $\frac{20}{40}$ with + $\frac{1}{18}$. L. V. = $\frac{2}{200}$.

September 29th.—L. V. = $\frac{2}{200}$. Ordered + $\frac{1}{18}$ for the distance and + $\frac{1}{8}$ for reading.

July 12, 1877.—L. V. = $\frac{20}{100}$ with + $\frac{1}{18}$.

This patient had no further trouble with his eyes. He lost his life in the Spuyten Duyvil Railroad accident of 1881.

There seems to be reason for believing that in his case the acute glaucoma was the result of a reflex irritation through the medium of the fifth nerve which was involved in the maxillary periostitis. At all events, the eye refused to get well, even after the iridectomy, until the offending teeth had been removed.

Case IX.—April 13, 1874.—S. A——, aged thirty-five, Sister of Charity, has been under treatment for several years, off and on, for granular lids with vascular keratitis. Five days ago she was attacked with a severe pain in and around her right eye. The eyeball was red, watery, and constantly painful. The pupil dilates very slightly after keeping the patient in the office half an hour and instilling atropine six times. Ordered two leeches to the temple and atropine six times an hour, three times a day.

April 18th.—Pain intense and unrelieved by anodynes and iced cloths. Tension increased; slight chemosis; some lymph in pupil. Counts fingers with uncertainty.

Dr. Agnew now performed an iridectomy upward upon the eye, the patient being under ether. Ordered atropine four times a day, and iced cloths.

April 21st.—Pain entirely relieved by the operation. Chemosis mostly gone. Sight gradually improving.

May 11th.—V. = $\frac{10}{200}$.

May 19th.—V. = $\frac{15}{200}$.

September 26th.—V. = $\frac{20}{40}$. The eye is quiet, and the impairment of vision seems to be due to corneal opacity.

It is a question whether, in this case, the vigorous use of atrophia, for the control of iritis, had anything to do with the causation of the acute glaucomatous symptoms.

Case X.—L. C——, aged seventy-three, agent, came under observation at the Manhattan Eye and Ear Hospital, December 5, 1876. He stated that he had never had any trouble with his eyes until about two weeks previously when, while sitting in the parlor one evening, he observed that he could not see as well as usual. Upon covering first one eye and then the other, he found that his right eye was nearly blind. The eye became slightly red, but not painful, and the sight has since remained about the same.

R. V. = $\frac{15}{200}$; L. V. = $\frac{20}{30}$; no improvement with glasses.

Ophthalmoscopic examination showed apparent atrophic excavation of both optic disks. The examination of the fundus of the right eye was interfered with by a haziness of the cornea, but the whole retina could be seen to be studded with small hemorrhages.

As the tension was increased, a diagnosis of chronic glaucoma was made, and an operation upon the right eye was advised.

December 11th.—His wife died since his first visit, and he has been under constant excitement. His right eye has been very painful, and the sight is reduced to perception of light. The opacity of the media has so increased that the fundus cannot be examined. The eye is very red and watery, and the increase of tension is much more marked than at the last visit.

December 13th.—Ether was given, and Dr. Agnew performed an iridectomy upward. The operation was done with a minimum amount of violence, and no iris was left in the wound.

December 19th.—The eye looks about the same as before the operation. There has all along been some pain and some leaking of the aqueous.

March 7, 1877.—The eye has remained red and hard and more or less painful, with dilated pupil, and opaque media ever since the iridectomy.

Enucleation was now performed by Dr. D. Webster, and was followed by very troublesome bleeding, which was stopped by pressure with charpie after four hours of continued effort.

This patient presented himself at the new hospital, in October, 1881, with great impairment of vision of his remaining eye. An ophthalmoscopic examination showed that his whole retina was sprinkled over with ecchymotic spots of various sizes. There was no opacity of the media, no increase of tension, no glaucomatous cupping of the optic disk, and the disease was set down as *retinitis apoplectica*.

The retinal hemorrhages in both eyes, the failure of iridectomy to relieve the glaucomatous symptoms of the right, and the persistent bleeding after enucleation of the eyeball, were probably due to degenerative changes which had taken place in the walls of his blood-vessels. His radial arteries, and such others as could be felt with the fingers, were evidently atheromatous.

The enucleated eyeball was examined by Dr. Abraham Mayer, then the pathologist of the hospital, and the following notes made as to its condition:

"Eye of natural size, and very firm and hard. Cut in vertical meridian. Retina detached all around, except at ora serrata, and choroid in this latter region also detached. Left half of lens has remained in place; not so right half. Cornea and sclerotic much thinner than normal. Thinning of sclerotic most marked. Vitreous humor very fluid. Eye measures in horizontal meridian 25 mm."

Case XI.—November 14, 1877. John W——, aged fifty-eight, was attacked with granular lids in 1861, and was under treatment by various "oculists" for eight or ten years. Fifteen months ago he had a relapse, and was again under treatment for a short time. His eyes have been pretty well since, and until two weeks ago, when the left became painful. He has since been treated with atropine and nitrate of silver.

R., $\frac{20}{100}$: $\frac{20}{70}$ with — $\frac{1}{18}$. L., $\frac{20}{200}$; no improvement with glasses.

Ophthalmoscopic examination shows opacities of both cornea. Fundus normal in both.

December 7th.—Has had cantholysis, and open-

ing of the tear-passage, and various applications have been tried without relief. Vision of left eye is reduced to $\frac{5}{200}$, and there is decided increase of tension. The eye is red and painful, and the corneal opacity has so increased that the fundus can no longer be seen.

An iridectomy was advised, and Mr. W. decided to submit to it without an anæsthetic. Dr. Agnew then proceeded to make an ordinary iridectomy wound at the upper margin of the cornea, and upon the withdrawal of the knife the aqueous gushed out with some force, but did not produce a prolapse of the iris. Upon attempting to seize the iris and draw it out of the wound it was found to be so friable that none could be withdrawn. The operation was completed by snipping out a bit of cornea at the outer angle of the wound to prolong the healing and allow aqueous to leak out.

December 10th.—No pain since midnight after the operation. Anterior chamber re-established for the first time to-day.

January 2, 1878.—R. V. = $\frac{20}{70}$; L. V. = $\frac{20}{100}$; no pain since the operation.

Remarks.—Of the eleven patients whose cases are reported above, five were males and six were females. Their ages ranged from seventy-three to thirty-five. Three were fifty-five years of age, two were sixty, and two were thirty-five. Of the men, four were married and one a bachelor. Of the women, three were married and three single, one of them being a nun.

In these eleven cases *fifteen eyes* were operated upon, one of them twice, making sixteen operations in all. Twelve of the eyes operated upon were affected with primary acute glaucoma, two with acute glaucoma, the result of granular lids and pannus, and one was a case of acute hemorrhagic glaucoma, or of glaucoma supervening upon *retinitis apoplectica.*

The result of the iridectomy was good in all the cases except the one last mentioned. It restored useful vision in thirteen eyes, in one eye it relieved the pain and permanently quieted the eye, but in the hemorrhagic case it was a complete failure, the patient gladly assenting to enucleation for the relief of pain.

A MEDICAL CURIOSITY.

By GUY HINSDALE, M.D.,

PHILADELPHIA, PA.

In 1668 William Ramesay, doctor of physic and physician in ordinary to his Majesty Charles II., published a work entitled "Helminthologia." The book is not only a good exponent of the state of medical knowledge of that time, but the author's style and the strange words that abound in the work make it a literary curiosity.

This is the introduction: "Worms the Subject, and worms the Readers, and a worm the Author of this Book; which must all ere long, be swallowed up of Eternity and be worm-eaten; the Author himself and the proudest Reader as soon as the Book, we are enclosed but in mud walls, and paper walls are as durable."

"Most people (if not all) of both Sexes, of all ages of man from the Womb to the Tomb, are incident to, and may be molested, and direfully tormented and cruciated, with several horrid and intollerable pains and most maladies, nay and even death itself from worms."

The author declares in the title-page that this affection "doth probably appear to be an Epidemical Disease, Killing more than either the Sword or Plague." He professes to treat of the "Various Causes, Signs, Diagnostics, Prognostics, the horrid Symptomes by them introduced, as also the Indications and Method of Cure. All which is Medicinally, Philosophically, Astrologically and Historically handled." The writer says that although "I take the liberty, now and then, for my own pleasure, a little to expatiate, and digress; yet all along, have more respected Matter than Words . . . I considered *Quid scribere, quam quo modo.* So many Books have such large Bodies; but when we look narrowly into them, we find them without Souls." This sentiment is by no means obsolete.

Worms are often alluded to as "vermin," a use of the word which is etymologically correct. Sometimes the author uses the tautology of "helmintick vermin;" in another place Avicenna is quoted as saying that "our bodies are seldome without these Cattle." They "infest also sometimes the Windpipe or Rough artery; nay the pericardion and the heart itself, is not exempt from these vermin."

The book is, of course, full of strange anecdotes. A story is told of "a Wench who was as if she had been possessed of a Devil and at sometimes could not be held by three men (such were her strong convulsive passions) who evacuated by vomit twenty-four pounds of stuff of all colours, twice a day, for fourteen days together, and afterwards great Balls of Hair, pieces of Wood, Pigeons-dung, Parchments, Coals, &c. and after all this, two pounds of pure Blood and then again, Coals and Stones some of them bigger than a wall-nut; besides she had strange fits of laughing, weeping and extasies and at length voyded a live worm by Stool, like unto an Eele of a foot and a half long."

Garlic, onions, and leeks are charged with "breeding many gross crude and indigested humors and fuliginous fumes, offending the brain and causing worms. Cucumbers are much more an unwholesome Food, hard of digestion, yielding but a gross, scorbutick melancholy juice, also sometimes, a crude and phlegmatic matter."

The circulation of the blood is described, Harvey having published his essay on the "Motion of the Heart and Blood" forty years before. Dr. Ramesay informs us that the blood is made of the chyle, "amalgamated with a Serum from the Lymphatics, passes through the subclavals, whence mingled with the Blood, it rushes into the vena cava and so goes into the left Ventricle of the heart, and by its motion, is cast into the Lungs through the pulmonary arteries, to be there as well defaecated of some Emplastic Immundities and excrementitious Crudities."

The author is deeply impressed with the serious nature of the affection, and, indeed, attributes to worms the production of almost all maladies. He says: "But Sots as we are in this most weighty matter, we are too remiss, marrying any deformed piece of mortality for a little money, when we are curious of the strain of our Horses, Doggs, Pigeons, Game-Cocks; and so frequently, we leave a Crook-Back'd, Flat nos'd, Bow Leg'd, Squint-Ey'd, Left Handed, ugly, infirm, Weesle Fac'd, Diseased, Half witted, Hair brain'd, Nonsensical, Gooscappical and Coxcombical, Worm-eaten Ideot, not only to possess our Estates, but our Names, and to build up our Families."

Our author concludes: "That my reader may be

encincted with Reason able to Renix the Hallucinations of that Pangenerical evil of envy and Ignorance which is a cacoethick malady; But especially that he may enjoy an orthostadian Judgment and not to be Depasct with that Truculent credulity which proves Sontick to most men, and an assured prodromos of Ruine; I thought it not amiss to aedipize some things and indigitate thee, wherefore others in this book are handled in that manner they are: Whereby I doubt not, but that the Judicious will suffragate for me and Parastate for my Integrity and candor in it."

ANTE-PARTUM HOUR-GLASS CONTRACTION, WHICH CONTINUED POST-PARTUM, ACCOMPANIED BY PROFUSE HEMORRHAGE.

By S. J. RADCLIFFE, M.D., A.M.,

WASHINGTON, D. C.

I was called at 1 A.M., May 19, 1871, to see Mrs. E——, resident of Georgetown, in her fourth labor. She said her previous labors had been difficult, and attended with much hemorrhage. I found her in the second stage of labor, expulsive pains every ten to twelve minutes, strong and active. The vertex presented in first position, parts soft and yielding; general condition good.

After one hour, I found very little progress. On introducing the finger and keeping it against the presenting part during a pain, I discovered the head would advance during the pain, and recede after the pain had gone, without gain. It would advance only with the uterus, the protrusion being governed more by the force of the abdominal walls than by the uterus itself.

Nothing daunted, however, I determined to give the natural powers every chance, as is my custom, and, having patience, not to "meddle" too much. The pains kept up well, and there were no signs of exhaustion.

At the end of the second hour, there was still only slight advancement. The head was still clasped by the os, but had not included the brows. Passing my finger up by the side of the head, I felt a hard, unyielding cordon, which seemed to embrace the fœtus around the chest, and placing my hands flatly, as in palpation, over the abdomen, during pain, I felt the fundus contract violently, and very little motion of the lower half of the uterus.

At five o'clock—four hours having elapsed—there were no signs of early delivery. The pains were active, and almost continuous, and yet the head had advanced but little.

Still having confidence in the powers of Nature to overcome the difficulty, to "tire out" the circular fibres, I concluded to wait another hour before making any further interference.

At six o'clock, the case not progressing satisfactorily, I administered chloroform and applied the forceps.

The chloroform was not given to complete insensibility, as I hoped to get sufficient relaxation without going so far; but it was continued for nearly two hours, during which time I used traction with the forceps, gradually but forcibly, teasing as it were, little by little, until about eight o'clock, when, fortunately, the child was delivered, after seven hours' hard labor. The child was asphyxiated, but soon revived.

Finding the patient was bleeding considerably, I at once introduced my hand to deliver the placenta, but found I could not reach it. The uterus was firmly contracted around the middle, and I could not get a finger through the small opening. I endeavored to overcome the stricture with all the power I could muster. I struggled on without relaxing my hold, one hand on the abdomen and the other in the uterus, and with main force boring my fingers one by one, and little by little into the stricture. After a great deal of labor and fatigue, being myself almost exhausted from the effort, and in a predicament in which I had no time, and hardly a thought, to send for aid; while the patient was bleeding profusely, the blood literally saturating the bed, and running in pools on the floor, I finally succeeded in getting my hand through the stricture, dislodging the placenta, which was attached to the fundus, and delivering it.

The patient was blanched, almost pulseless, with sighing respiration, and could not speak above a whisper.

After the use of ice, friction, ergot, stimulants, and application of the binder, the uterus having contracted well, the hemorrhage ceased, and the patient eventually had a good recovery.

Never before in my life had I been placed in such a strait, or compelled single-handed to contend against such odds, and I think never since, and it is not often the termination of such a case is so fortunate.

ON THE HISTORY AND LAWS OF THERAPEUTICS.

By JOHN C. PETERS, M.D.,

NEW YORK.

Dr. Edward R. Squibb, in his "Ephemeris of Materia Medica and Therapeutics" for May, 1882, page 70, says:

"A physician who believes in *opposing* the tendencies of disease by agencies which *counteract* such tendencies, can never get any help from consulting with one of *directly opposite* doctrines—one who believes that *like cures like*. Neither can the latter get any help from the former. In any consultation between the two, one or the other, as the first step, *must* (?!) give up the principles upon which his practice is based. The patient cannot have the alleged benefits of both, because they are in *antagonism* (2?!)"

In the above quotation the italics are mine, and also the question and exclamation marks. Dr. Squibb seems to take it for granted that there is only one law in therapeutics, and that is *contraria contrariis curantur*, or the cure by opposition, antagonism, counteraction, or perhaps neutralization. But diseases are cured in many different ways. Even Hippocrates, in his "Treatise on Ancient Medicine," says: "*Diseases are sometimes cured by contraries, sometimes by similars, and sometimes by remedies which have neither similitude nor antagonism.*"

Although Hippocrates was born B.C. 460, his opportunities for the observation and study of disease and its history had been abundant. He was brought up among the Asclepiadæ who were attached to the Temple of Cos; from a very early period of his life had access to all the records which were accumulated there, besides seeing numberless sick persons. He was also the eighteenth in lineal descent from a family of physicians, and a pupil of Democritus, Heraclitus, and Herodicus, who were among the

most illustrious followers of Pythagoras. He lived in the age of Pericles and was his physician, and was the friend and medical adviser of Plato, Socrates, Sophocles, Aristides, Phidias, Praxiteles, and others, such as Eschylus, Euripides, Herodotus, Thucydides, Demosthenes, and Epaminondas.

GALEN, born A.D. 131, established the one-sided laws: "*Health is maintained by supplying similars with similars; Disease is overcome by opposing contraries to contraries.*"

PARACELSUS, born A.D. 1493, proclaimed: "*Contraria contrariis is false,* and never did hold true in medicine. It is well done when we oppose like to like. Know all men that like attacks its like and never its contrary."

HAHNEMANN, born A.D. 1755, or one hundred and twenty-seven years ago, perpetuated the system of Paracelsus, aided by mesmerism, magnetism, and other frivolities.

The great mass of the medical profession have followed the rules of Hippocrates. It has never come under the yoke of any one system or law of therapeutics. Observation and experience have been its main guides, and hypothesis and false theories have only been its amusements and recreations, not its masters.

More than twenty years ago I adopted the broad and pure principles of Hippocrates after abundant opportunities of seeing recoveries from disease, both here and abroad, in many, perhaps all probable ways, viz.: by expectancy, or the *vis medicatrix naturæ*, by regular and homœopathic treatment. Hippocrates simply makes a statement of fact; I thought and still believe that I hit upon an explanation or true theory, *i.e.*, a legitimate deduction from many facts, not contradicted by other and equally well substantiated facts, which may thus be summed up: OPPOSITION or antagonism is merely the *greatest* possible amount or *degree of difference.* SIMILARITY is not *identity*, but always includes some difference, and may be defined as the *least or lesser degree of difference.* DIFFERENCE is neither antagonism nor similarity, but may, often does, include more or less of both. All cures take place by bringing about an alteration or change in the action of the disease, or by substituting a differential or alterative action. The remedy must always act differently, and this difference may be so great as to amount to antagonism, or so small as to approach similarity. The true theory and practice of medicine is alterative or substitutive. Remedies which act somewhat similarly, yet sufficiently different from the action of the disease, may and must cure, provided the dose and power of the remedy be great enough to alter or change, or substitute itself for the action of the disease; because only something different can alter or change, or counteract, or substitute itself. Two different actions cannot go on at the same time, in the same place. Thus, theoretically, homœopathy, or like cures like, is absolutely incorrect and untrue. Practically, it may be occasionally available. It, at its best, is only a fragment of a far greater and broader law, that of alterative or differential, or substitutive action. It may be regarded as the shadow of a truth, or the smallest end of the tail of the allopathic rite. Infinitesimal doses are absolutely inoperative, and all so-called cures by them must be regarded as accidental or fortunate recoveries. Those homœopaths who use tangible doses must be regarded as fractious and unreasonable allopaths. Those who use the remedies and doses of the regular school may be looked upon as erring brethren who have placed themselves in such a false position that they can only be rescued by great kindness and consideration on the part of their more numerous and powerful fellow-practitioners.

All the great modern advances in therapeutics have been made in the regular school, which must be regarded as the newest, most progressive, and by far the most scientific one. Homœopathy has made no advances in its own direction during the last twenty-five years, and must be regarded as an old, almost effete, and dying system, which would long ago have ceased to exist as a school if its adherents had not adopted so much from the regular school.

Progress of Medical Science.

IMPORTANCE OF EARLY DIAGNOSIS AND TREATMENT OF CARIES OF THE SPINE.—The importance of detecting spinal caries is urged by Dr. Edmund Owen, Surgeon to St. Mary's Hospital, etc. He finds that very frequently caries is not diagnosticated until the spine has assumed the typical angular deformity, whereas treatment of its cause should aim at precluding just that deformity. He draws as parallel instances the danger of delay in forming a diagnosis in knee-joint inflammation until after the typical "fiddler's bow" flexion is attained or the equally reprehensible delay in diagnosticating and operating for mammary scirrhus until the axillary glands become enlarged. In regard to treatment, Dr. Owen is of the opinion that when taken during the inflammatory stage, at the onset, complete rest on a hard mattress bed for a few weeks will suffice. If of later detection, rest followed by a plaster-of-Paris jacket, moulded to the form from the great trochanters to the axilla, will usually prove successful. The author is in favor of the plaster jacket as described and applied by Dr. Sayre of this city, above all others.—*British Medical Journal*, May 13, 1882.

IODOFORM IN ENLARGED AND ULCERATED TONSILS.—Dr. Henry describes a number of cases of tonsillar hypertrophy and ulceration which he claims to have cured by the use of iodoform in the form of spray. He was thus able to get the local effects of a strong solution, made by dissolving the powder in ten parts of strong sulphuric ether. He says that the value of iodoform is now conceded by all those who have had any experience in its use in this class of affections. The difficulties in depositing it on the surface of the glands have deterred many from adopting it in every-day practice. It must be admitted that on this account it has not met with the universal adoption it really deserves. In powder it is easily deposited over the surface of a wound, or an etherial solution can be passed over a surface that is exposed to the air; but this is difficult in the case of the tonsils and pharynx, and especially over the posterior portion of the tonsils. To be "done well," and to accomplish the purpose with the least pain and annoyance to the patient, it must be "done quickly," almost instantaneously. The use of very strong, specially constructed spray-tubes and the use of compressed air, with a very heavy pressure, appears to be necessary for this purpose. His own apparatus was constructed by Dr. Saas. Three such tubes are essential—one turned downward, one straight, and the third turned upward. With the first, the

larynx and surrounding lower parts can be treated; with the straight tube the middle part of the throat, pharynx, fauces, palate, and anterior portion of the tonsils can be sprayed. The posterior portion of the tonsils can only be sprayed with the tube with the downward curve. To do this well the patient must be artificially excited to the effort at retching. By so doing the tonsils are turned forward and sideways, thus enabling the operator to pass the curved tube behind the posterior portion of the glands. In some this effort at retching is involuntary on the slightest provocation. It can be easily induced by tickling the palate with the end of the tube. The deposit of the iodoform with the apparatus described is almost instantaneous, and is easily controlled, and can be directed to any spot. With the first expiration of air following the withdrawal of the tube, the ether is evaporated and expelled, leaving the iodoform well impressed on the glands and surrounding mucous surfaces. The coating is of a pale yellow color, and with the evaporation of the ether all unpleasant sensation is removed. The slight pungent taste and odor of the ether passes off entirely with a few fresh inspirations and expirations. Care must be taken with the tubes, for they are easily filled up with crystals that are difficult of removal. When the iodoform is first exposed to the action of the ether in the proportion mentioned, it is perfectly soluble. When the ether has been evaporated the remaining iodoform in the tubes crystallizes, and is not again soluble to the same extent.—*New England Med. Monthly*, June 15, 1882.

The Length of the Intestine, according to experiments of Tarenetzky, is, to the length of the body: In a five months' embryo, 1 to 4.2; in the infant at birth, 1 to 5.9; in infants under one year, 1 to 6.6; in children up to the sixteenth year, 1 to 7.6; in adults, 1 to 7.2. The body length was measured from the vortex of the skull to the upper border of the coccyx. In old age the intestine is relatively shorter.

Prodromata of Phthisis.—Dr. Coiffier (*Lyon Médical*, December, 1881) is inclined to believe that when a clean tongue coexists with a pulse of eighty-five it is an almost certain prodromus of pulmonary phthisis. When found in persons between eighteen and thirty years of age, who seem to be in excellent health, Dr. Coiffier regards such coexistent symptoms as evidence that tubercular deposit has already occurred.—*Chicago Medical Review.*

A New Antipyretic.—Macalline, an alkaloid obtained from the bark of the macallo, a tree which grows in Yucatan, is recommended by Dr. Rosado as superior to quinine in the treatment of intermittent and remittent fevers.

Lutidine as an Antidote for Strychnia.—Messrs. Greville Williams and Waters have discovered (*British Medical Journal*) an antidote for strychnia in the organic base, first prepared by the former, by distilling cinchona with caustic potash, and to which he assigned the name *beta* lutidine. Having ascertained, by experiments upon frogs, that *beta* lutidine causes a distinct increase in the tonicity of both cardiac and voluntary muscular tissues; also retardation of the heart's beat; that it arrests the inhibitory power of the vagus; and that by its action upon the nerve-cells of the spinal cord, it, in the first place, lengthens the time of reflex action, and then arrests that function; they proceeded to test its direct counter-action to strychnia. The brains of frogs were destroyed in the usual way. An animal was then treated with *beta* lutidine till reflex action disappeared, when the subsequent administration of strychnia was not followed by the usual results. To another frog strychnia was given till strychnia tetanus was produced, when it was found that the subsequent administration of lutidine caused the tetanus to pass off. The almost simultaneous administration of the two bases was not followed by tetanus. It is not unlikely that a substance so powerful will have some positive therapeutical value.

Statistics of Insanity in the United States.—Dr. C. L. Dana gives (*Journal of Nervous and Mental Diseases*, April, 1882) the following statistics regarding the insane in this country: We had in 1880, in round numbers, 89,000 (to 96,000) insane, which gives a ratio of 1-570 (1-520) of the population. The census ratio in 1860 was 1-1,310; in 1870, 1-1,100; in 1875, 1-953. Our population increased in the decade 1870 to 1880 about 26 per cent., while our insane population has apparently increased over 100 per cent. As regards the *distribution of insanity* and of its *increase*, the proportion of insane is greatest in New England, where the ratio is 1 to 357. Here, however, the rate of increase is becoming slower. In proportionate number of insane, after the New England and Pacific States, come the Middle States (1 to 446), then the Western (1 to 570), and then the Southern (1 to 780). As regards asylum accommodation: In 1881 we had 74 State and 14 large private asylums, with a capacity approximately for 31,900, but holding 39,145. At a very low estimate, therefore, our asylums are overcrowded to the extent of 10,000 patients, while there are about 50,000 who are not in any asylums at all. Regarding the cost of asylums: We have about $40,000,000 invested in these institutions, at an average cost of over half a million apiece. It takes about $8,000,000 a year to run them, or $82,000 for each institution, not including interest. If we should add interest the total annual expenditure for the care of the insane amounts to $12,000,000. The annual cost per patient has been variously estimated at from $166 to $316.

Differential Staining of Nucleated Blood Corpuscles.—Dr. Allen T. Moore, of Ann Harbor, Mich., describes and figures (*The Microscope*) his method of double staining of nucleated (red) blood-corpuscles. He prepares two fluids for this purpose, called A and B. The first, A, is composed of eosin, gr. v.; aquæ distil, ʒ iv.; alcohol, ʒ iv. The fluid B is composed of methyl analin green, gr. v.; aquæ distil, ℥ i. The blood is spread upon a slide by placing a drop upon one end and quickly drawing the smooth edge of another slide over it. When the corpuscles are thoroughly dry the slide should be flooded with stain A. This should be allowed to remain on for about three minutes. It is then washed in clean water and flooded before dry with stain B. In two minutes the slide should again be washed and set away to dry. When dry a drop of Canada balsam is put upon the blood, a cover glass applied, etc. The red corpuscles will now be found to be stained red, while the nuclei and leucocytes are stained green.

Self-Hypnotization as a Remedy for Sleeplessness.—Dr. B. Greidenburg relates (*St. Petersburg Medicinische Wochensch.*) the history of a patient with athetosis, who suffered from obstinate insomnia. He used to get relief finally by fixing a light so that its reflection was visible in a glass of water. After gazing fixedly upon this he, according to Greidenburg, would fall off in a hypnotic condition and sleep.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, August 5, 1882.

THE SOCIAL RELATION OF THE DOCTOR TO HIS PATIENT.

So seldom are things said which directly concern the physician himself in his relations to his patients and neighbors, that we see no reason why any occasion for so doing, as will appear further on, should be neglected. Every medical man formulates for himself a set of rules for guidance in the so-called social treatment of his patients, and instinctively falls into a line of conduct which fits in turn the requirements of the pauper and the millionnaire, and makes him, as the physician, the right man in the right place, no matter to whom he may be summoned. Some men succeed in this respect better than others. Indeed, the disposition to adapt one's self to circumstances, the faculty of being agreeable at all times, and of inspiring confidence among those who in their due emergencies look to a physician for help, are oftentimes more necessary to the would-be successful man than a thorough knowledge of his art. The patient being better able to judge whether or no his physician is a gentleman than a well-educated medical man, will be most inclined to make a choice in the easiest and most natural manner. Hence it follows that the most successful practitioner is not always the most learned man. It is a pity that the ordinary condition of success does not oftener couple itself with sound scientific attainments, that practical tact so frequently dodges ahead of solid worth, and so invariably wins in the life race. But the rule is otherwise, as most of us know. In every community there are examples of success and unsuccess which fit both of these extremes. There, for instance, is the affable man, who is loved by the children, adored by their mothers, and trusted by their fathers, whose ignorance of his profession is never once suspected, and who rides into a lucrative and pleasant practice, while his brusque, matter-of-fact, and scientific neighbor is almost starving. Every one who knows how much sunshine is wanted in a sick room, can hardly blame the patient for his preferences.

It is an old and a true saw, as applied to medical practice, that faith is half the battle. The man who can inspire the proper amount of confidence in his skill has no occasion for the multiplication of prescriptions. To do this effectually with all classes of patients requires a rare knowledge of human nature, and a wide range of adaptability to attending conditions. Without some of the necessary tact to such an end medical knowledge does not avail much. Patients will be suited in their own way. Coarseness in a physician is not tolerated any more as an eccentricity of greatness. The Abernethy's of to-day are at a discount, and even their superior learning cannot gain an entrance for them into refined and polite society. Patients, now-a-days, do not think it necessary to have their little social preferences ignored even by the man who may be able to save their lives. But this is well enough known not to need special reiteration here, save for the excuse of calling attention to an interesting and instructive little work,[1] lately published, devoted to the general consideration of the social relations of the physician to his patient.

The worldly man is, as a rule, a man of experience. He does not usually become wise in his day and generation until the day is pretty well advanced, and his generation under quite a good headway. Hence this knowledge, so difficult of attainment and so slow of acquirement, has a peculiar value to its possessor. The physician who can fortunately gain it before his pitcher is broken at the fountain, or his windows become darkened, is generally the envy of his fellows, because he starts well and, as a rule, comes out ahead in the end. He can enjoy his bread before the grinders at the mill are few, and can get near the hilltop before the grasshopper becomes a burden.

It would seem that the importance of the knowledge of which mention has been made, is not sufficiently appreciated and that, as a rule, the gentler graces and dignified deportment are not sufficiently cared for. In the fierce struggle for professional distinction, the desire to be informed upon the latest surgical eviceration, the determination to see the latest bacillus and, if possible, to discover another; the ambition to wrestle with the last problem of vaccination, and in all things professional to do and dare, and still go on, are so overpowering that all else appears to be lost sight of.

Truly says our author in his entertaining and instructive brochure:

"Professional tact and business sagacity are as necessary to the physician as the mariner's compass

[1] The Physician Himself and what He should add to the Strictly Scientific. By D. W. Cathell, M.D., late Professor of Pathology in College of Physicians and Surgeons, Baltimore, etc. Baltimore: Cushings & Bailey, 1882. 8vo, pp. 194.

is to the navigator. There are gentlemen in the ranks of our profession who are perfectly acquainted with the scientific aspects of medicine, and can tell you what to do for almost every ailment that affects humanity—who, nevertheless, after earnest trial, have never gotten either reputation or practice, because they lack professional tact and business sagacity; and there is nothing more pitiful than to see a worthy physician, deficient in these qualities, waiting year after year for practice that never comes."

The question, from this standpoint, narrows itself to what shall be added to the strictly scientific education of the physician to make his success in practice more certain, more rapid, and more complete than is usually the case.

In advising the reader to this end, Dr. Cathell goes over a great deal of ground. It is not to our purpose to follow him step by step, but rather to take a general look over the field and here and there gather specimens of the author's experience of men and things which may serve to give an idea of his work as a whole. So much depends upon the man himself and his surroundings, that we are not surprised that the author is so plain spoken on the matter of personal make-up. Happily this advice is not needed save in quite exceptional cases, but its importance cannot be overestimated even by the man of most fastidious taste. In fact, it is generally through this medium that the doctor makes one, at least, of his earlier impressions upon his patient.

"If you dress well, people will employ you more readily, accord you more confidence, expect a larger bill, and will pay it more willingly. You never heard of a bank swindler, or a confidence man, or a counterfeiter, or a pseudo gentleman of any kind, who dressed shabbily or appeared coarse. Such people are all close students of human nature, and no matter how abandoned they are, no matter how tarnished their characters, nor how blackened their hearts, they manage to hide their deformities as with a veil from all but the few that know of their true characters by assuming the dress and manners of gentlemen. Now, if genteel dress and polished manners can do so much for such fallen specimens of mankind, how much greater influence must they exert for those who are truly gentlemen and members of a lofty profession." And the same remarks apply to the appearance of the office, the style of the equipage, the genteel manner of living, and even the character of the sign at the door-post. It is beyond question that nothing can be lost in a dignified appearance and correspondingly tasteful surroundings.

Generally the person who is sick is uncompromisingly æsthetic, and it is to such that the physician must minister to in more ways than one. It is sometimes quite hard to convince even well folk that the dinner is not particularly tasty at a well arranged table and that the material and shape of the glass has not a great deal to do with the flavor of the wine. But sick people are much more unreasonable, and we are taught that we should be always ready to humor them.

In all this endeavor to be pleasing, however, there may be a danger of overstepping the mark, by being tempted to gossip. As well said by the author, when you have finished talking to the patient about his case, nothing more and nothing less, your visit is virtually at an end. And here the necessity of minute examinations of the patient cannot be too strongly insisted upon. A patient or his friends can never be plied with too many questions concerning possible symptoms, while a neglect to ask what may by them be considered important is, as many physicians have known to their sorrow, fatal to a real confidence in their skill.

It need hardly be said that in this little work, which contains so much, the discussion of the matter of pecuniary relations of patients to the doctor are not in any wise neglected. And with a quotation or two on this point we reluctantly close, at least for the present, our rather discursive remarks upon the general subject under consideration.

After referring to the fact that pure professional devotion will not be considered, by the butcher and baker, as a good reason why the doctor and his family should be fed for nothing, and that man, no matter how scientific and disinterestedly good, cannot live on philanthropy alone, the reader is prepared for the hard and rather unpoetical statement that "the nearer your financial department approaches the cash system the better for you and your family. It is often more advisable even to submit to a reduction in a bill for cash than to let the account stand and run the risk of losing it. After settling promptly, many patients will feel free to send for you again, and make another bill, even in moderate sickness, instead of dallying with home remedies or quack medicines. You should present your bills while they are small and your services are still vividly remembered. If you are neglectful or shamefaced, and do not send your bills promptly, it will create a belief that you are either not dependent on your practice for a living or that you do not hold this or that person to your business rule, or are not uneasy about what *they* owe you, or that you are rich and do not need money, and if you foster such notions a bad system will grow up around you and great and irreparable loss will result. . . . Besides, time effaces details and recollections of numbers of visits, the doctor's watchings, cares, and anxieties are also forgotten, and the bill, although really moderate, is apt to look large. All these considerations combined are apt to make people feel, when they do pay an old bill, somewhat as if they were doing a generous thing, and making the doctor a present of that amount."

With all of which every sensible man must agree. We believe that there is nothing which will more surely make the heart of the expectant doctor sick, than the contemplation of his lost opportunities in the collection of long-standing accounts. But the doctor's widow and family will be destined to know even more about it than he does, when the time comes for them to square accounts between his reputation and their poverty.

HOTEL DOCTORS.

A LETTER has appeared in a hotel paper upon the subject of "hotel doctors." The writer is a gentleman who had been travelling with his family. He was taken sick at a hotel and was attended by the resident physician. There is an indignant description of the way in which he was, as he claims, "robbed" by the doctor. The medical service furnished was trivial, yet the physician persisted in calling often and finally sent in a very large bill. It is, we are told, ingeniously arranged so that the doctor's bill can be collected at the desk. There is no other way than to pay, therefore—a hardship indeed to most people. The case related by the correspondent in question is unfortunately only one out of a large number. There have been, indeed, so many hotel doctors who have used every expedient and excuse to increase their charges that the term hotel—as attached to a physician—has begun to carry some reproach. This is unfortunate, because a large number, and probably the majority of this class are, by no means extortionate, but are gentlemen having more than ordinary professional skill and social standing.

There is something in the environment of a modern fashionable hotel, which explains, if it does not palliate the rapaciousness of its physician. The hotel-keeper uses every means which is legally possible to wring money out of his guests. And if the hotel doctor, whose expenses are very great, imbibes some of the same spirit it is not perhaps to be wondered at.

The hotel doctor who practises at summer resorts is rather a modern institution. But the same stories of unreasonable charges are circulated about him. We can say the same thing regarding these accusations: that in some cases they are very just, in more cases they are only what the physician's expenses oblige him to ask. The convenience of having a medical man in a hotel must be paid for. But hotel doctors should remember that they have no right to bring the profession into reproach by tricky devices for increasing their bills. Good pay for good service rendered is a proper motto for this as well as every other class of medical men.

THE MINIMUM LIMIT OF EXERCISE.

FREDERICK THE GREAT is reported to have said: "When I consider the physical structure of man, it appears to me as if nature had formed us rather to be postilions than sedentary men of letters." The belief that such was nature's real purpose seems to have taken hold of an eminent London hygienist, Dr. B. W. Richardson. At a recent lecture, delivered before the Ladies' Sanitary Association, he declared it essential, as a matter of principle, that eight hours of the day be devoted to exercise, care being taken only to avoid "monotony of movement." Such a statement has naturally excited much criticism and incredulity. The London *Spectator*, commenting upon it, asks why the medical profession does not formulate its opinion about the indispensable minimum of exercise, as was done some time ago about the expedient maximum of alcohol.

Such a formula would certainly be a great sanitary help and convenience, but it is impossible to give it with any preciseness. The minimum amount of exercise consistent with good health must vary with the habit, occupation, and the physical organization of the individual. We do not know that any one can come any nearer to a correct formula than old Christopher Hufeland, who, a hundred years ago, wrote: "I consider it, therefore, an indispensable law of longevity that one should exercise at least an hour every day in the open air. The most healthful time is before meals, or from three to four hours after." Horseback riding, dancing, gymnastic exercise, and walking are the measures which he recommends in detail; and he adds what every one admits, that that exercise is best which interests the mind as well as occupies the body.

Persons whose physique or occupation is peculiar must depart from the above rule, but how or to what extent a study of each case is necessary to determine.

THE ANTIPYRETIC ACTION OF ALCOHOL.

DR. L. GREBE communicates the results of some experiments upon the antipyretic action of alcohol (*Archiv. für wissensch. u. pract. Thierheilkunde*).

A large dog was taken, and hourly observations of its temperature made, so as to obtain the normal daily curve. The same observations were repeated on two dogs, and, at the same time, the effect of giving cold water, in three to five-ounce doses, was noted. A dog, weighing twenty-one pounds, had then an artificial fever produced by the subcutaneous injection of pus. Fifty grammes of alcohol and one hundred grammes of water were then given, and the temperature noted every half hour. There was a steady fall, during the next three and a half hours, from 40° C. to 39.1° C. Next day the temperature had risen to 40.6° C. One hundred grammes of alcohol were given. It was followed by a steady fall, which, in two and a half hours, amounted to 1.5° C. Another dog was treated in the same way, with similar results.

The next series of experiments was upon horses.

The first animal was suffering from an inflammation of the joint, which excited a fever amounting to 40.5° C. (105° F.). The horse was given one hundred grammes of rum, corresponding to a little over an ounce of pure alcohol, every two hours. There was a temporary increase in temperature of between 1° F. and 4° F. The total effect, however, after twenty-four hours, was a reduction of temperature to 38° C., giving a fall of 2.5° C. (about 4.5° F.).

This experiment was repeated upon four other horses, the conditions being varied somewhat.

The conclusions drawn by Dr. Grebe are as follows:

First.—The action of alcohol upon the temperature varies, according as it is given, in small or large doses.

Second.—In small and moderate doses alcohol, when given to animals with fever, produces an immediate slight increase in the bodily temperature, amounting to about 1° F.

Third.—This increase is of short duration, and is followed by a fall of temperature to a lower level than before the alcohol was taken.

Fourth.—In large, but not poisonous doses, alcohol depresses the temperature without any previous rise. The fall may amount to several degrees.

Fifth.—A long-continued fall of temperature can only be obtained by giving large doses at regular intervals. Given in this manner, alcohol is a true antipyretic.

Sixth.—Alcohol has its antipyretic effect by virtue of its power to hinder or lessen oxydation. The author states that in fever the red blood-corpuscles are diminished in number, but that by giving alcohol in antipyretic doses they reach their normal amount again. This assertion, first made by Manässein, was confirmed by Grebe.

The various theories offered to explain the heat-depressing powers of alcohol are discussed by our author. He is inclined to give the most weight to the power which alcohol has of delaying tissue-changes. Grebe's conclusions are in harmony with those of most of the other very numerous investigators in this line.

DR. KINLOCH'S CASE OF DEATH FROM CHLOROFORM.

The case of death from chloroform reported by Dr. Kinloch, of Charleston, S. C., in another column, is a notable one not only on account of some very unjust criticisms concerning it in the secular press, but also as furnishing another proof of the danger of chloroform even in the most skilful hands. Here was an instance in which a distinguished surgeon, of large and varied experience, used a remedy which he had trusted many hundreds of times before, and yet in which, in the twinkling of an eye, the patient passed over to death.

In the South, as abroad, chloroform is the favorite anæsthetic, but the moral to be drawn from each fatal case of narcosis from its use is always the same. The issue is met by our correspondent in a straightforward and manly way, and the charge by the daily press, that any concealment was attempted by Dr. Kinloch, must be looked upon by all who know him as simply absurd. We, in common with the profession at large, sincerely sympathize with him in his mishap.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 10, 1882.

DR. E. C. SEGUIN, PRESIDENT, IN THE CHAIR.

DR. N. BOZEMAN presented three specimens:

THE UTERUS CONTAINING SEVERAL SUBPERITONEAL FIBROIDS AND SUBMUCOUS POLYPI—AN OVARY ILLUSTRATING COMMENCING CYSTIC DEGENERATION—ONE OF THE FEMORAL VEINS CONTAINING AN OLD THROMBUS.

All the specimens were removed from the body of a woman, upon whom he performed ovariotomy April 22, 1882. The following was the history of the case: The patient was fifty-two years of age, and had always enjoyed good health until the summer of 1880, when she first noticed an enlargement of the abdomen, which grew with considerable rapidity, occasioned considerable distress, until the summer of 1881, when she consulted Dr. Smith, of St. Lawrence County, N. Y., who diagnosticated ovarian tumor, and removed, by tapping, twenty pounds of fluid, having the consistence and color of syrup of tolu. The tapping was repeated seven months afterward and twenty-eight pounds of fluid, having a similar color and consistence, were removed. In the latter part of February last, he drew off thirty-five pounds, making in all eighty-three pounds of fluid removed by tapping.

On the 11th of April she entered Dr. Bozeman's service at the Woman's Hospital. At that time she was much emaciated, her abdomen was symmetrically enlarged, measured forty-four inches in circumference, fluctuation was distinct, and there was dulness over the left lumbar region. Diagnosis of ovarian tumor was made, and the patient was put upon treatment preparatory for ovariotomy, which was performed on April 22, 1882. The tumor was exposed, and there being but adhesions, the large cyst was removed, which, together with the fluid it contained, weighed 40¼ pounds. It had a broad pedicle which was secured in the usual manner by a double ligature. On examination of the right ovary it was found to be about the size of a pullet's egg and fluctuating. It was removed in the usual manner, and found to have a multilocular cyst in the centre lined with ciliated epithelium, the walls consisting of the stroma of the organ. It contained fluid of the same character as that found in the large cyst.

The uterus was examined and found to have some half dozen subperitoneal fibroids, varying in size from that of a pea to a walnut, and occupying the fundus and anterior wall. It was not removed. The peritoneum was carefully cleansed. There was no hemorrhage, but considerable "sweating" from the serous surfaces. The external incision was closed

with interrupted silk sutures, and antiseptic dressings applied. The patient was returned to the bed in fair condition. Temperature, 99⅘° F.; pulse, 108; and respiration, 24. The case progressed favorably until the seventh day when she was removed from the cottage to the building, her highest temperature being 100⅘° F., the average being 99⅕° F.; the highest pulse 108, the average 80 to 90. The after-treatment consisted of nourishment, quinine, brandy, and opium.

On the third day a peculiar symptom developed, namely, *numbness and feeling of weight in the right arm and leg*, so that the patient could not move either of them. Her mental condition at the same time seemed sluggish. Examination of the afflicted limbs revealed nothing peculiar. There was some difficulty of articulation, which continued for twenty-four hours. The numbness continued more or less for twenty-four hours. *There was at no time*, either *before or after the operation, œdema of the extremities*, a remarkable fact when taken in connection with a condition to be mentioned hereafter. During the patient's stay in the cottage the urine was examined daily, and was normal. On the day she was removed to the building, the pulse and temperature were normal. The sutures were removed by Dr. Goldthwaite and the wound looked well, although there was slight suppuration at the lower angle. On the ninth day, two days after removal to the building, the temperature rose to 103° F., and pulse to 120. There was no chill. Under the use of quinine and the application of the ice-coil to the abdomen, the temperature, within eight hours, fell to 99⅕° F., pulse to 99. On the next day the temperature rose, but fell under the use of the coil, and so continued varying from 99⅕° F. to 102⅘° F., until the 15th day, when the pulse rose to 160 and the patient died. In the meantime the external wound had healed, and there was no pain on palpating the abdomen.

At the autopsy made by Dr. Welch, it was found, on prolonging the original incision in the abdomen, that the recti muscles were honeycombed with cavities, containing a thick, greenish yellow, acrid pus. The parietal and visceral layers of the peritoneum were glued together, and coated with a thick fibro-purulent exudation. The intestines were matted together. The spleen contained no infarctions. The kidneys were normal. The stomach presented the lesions of chronic gastritis, and Peyer's patches exhibited the shaven-beard appearance. Douglas' cul-de-sac was obliterated by adhesions. The rectum was deeply congested and considerably distended. The mucous membrane of the bladder was inflamed and covered with muco-purulent material. The uterus had the fibroids already mentioned, and its length was only slightly above the normal. From the mucous surface of the lower part of the cervical canal hung a small polypus; and at the fundus especially were small "fungosities" which were mostly sessile (one or two polypoid).

Both ovaries were absent. On the *left* side the pedicle was made up of the broad ligament, Fallopian tube, and ovarian ligament. The ligature was buried from sight by recent adhesions. One additional ligature was discovered on this side, including an adhesion. *Right* side: Pedicle included same structures as on opposite side, except the *round* ligament. The intestines were adherent to pelvic organs and to pedicles covered with similar exudation. There was about a litre of dirty purulent fluid in the peritoneal cavity, enclosed in separate cavities by adhesions. Tympanitis moderate.

Diaphragm pressed up to second intercostal space on right side to third space on left.

Heart: Small, but normal. Few atheromatous patches on mitral valves and at beginning of aorta.

Right lung: Old pleural adhesions. Emphysema well marked along anterior border. Some attendant œdema.

Left lung: Slight emphysema; hypostasis of inferior lobe. No infarctions.

A most interesting feature of the case was the presence of old thrombi in both femoral veins, the *left* being completely occluded, as was the corresponding *saphenous* vein, the *right* not entirely so. Extending from the two common iliacs up to the vena cava inferior, to a point two centimetres below the origin of the renal veins, was a parietal thrombus of comparatively recent origin, with an attendant *adhesive phlebitis*. In some places the lumen was entirely closed, in others a narrow channel was left. No evidences of embolism were found with such an extensive thrombosis. The pelvic plexuses were also thrombosed, even the smallest veins being occluded. The brain was not examined.

THE PRESIDENT remarked that the numbness and disturbance of articulation were very interesting symptoms, and the hemiplegia was susceptible of one or two explanations: (1) Embolism produced by detachment of some particles from diseased cardiac valves, or (2) minute emboli from the thrombosed veins went to the right side of the heart, through the pulmonary circulation to the left side of the heart, thence through the aorta to the left side of the brain. The occurrence of the last form of embolism is not generally recognized, but that it takes place has certainly been demonstrated by experiments on animals. The second variety of embolism serves to explain the hemiplegia that occurs in the puerperal state.

DR. A. F. LIAUTARD presented a specimen illustrating

FRACTURE OF THE SPINE IN THE DOG.

It was accompanied by the following history. In January, he received a small female pug, about six weeks old, which was rachitic, all the legs being deformed, the body emaciated, the head very large, the eyes prominent, and she was scarcely able to stand or take nourishment. She was so well bred that he endeavored to save her life, and she was fed with meat and beef extract, and given lime and salt. About the beginning of March she had developed into a handsome dog, in apparent health, with the exception of a general eczema, probably due to mode of feeding. One evening, early in March, she was suddenly seized with an epileptic fit, fell from the lap to the floor, and did not recover for several hours. After recovery she was completely paralyzed for forty-eight hours. She was nursed, and on the third day she could raise her head, moved one fore leg, then the other, and at the end of about a week seemed recovered from the loss of power except in the hind quarters, which from the dorso-lumbar articulation were entirely paralyzed. Nux vomica was administered and electricity applied. Sensation returned to the hind legs, they would move when irritated and she could carry them to the mouth and bite them, but she was unable to get up. If raised, she could not stand, and when held up, her vertebral column presented the normal outline from the neck backward as far as the posterior part of the back, where it suddenly raised and formed an upward curvature. All the parts below this point were

paralyzed. She was treated for four weeks, but in vain, and finally chloroform was given and a post-mortem examination made. All the internal organs were normal, except the intestines contained several lumbricoides, often the cause of epileptic fits in young dogs. The spinal column exhibited a fracture at the eleventh dorsal vertebra, and apparently no repair had taken place, due, probably, to the diseased condition of the bones.

DR. ROBERT NEWMAN presented

A TESTICLE,

with the following history.

C. W——, aged thirty, married, came under treatment March 15, 1882. He had been ailing since September last, but had been sick abed and under the medical advice of several practitioners for nearly three months. His right testicle was enlarged, swollen, and has caused great pain, sometimes even excruciating, preventing any sleep. His general condition is good. Bowels are costive; often has severe colic pains. The testicle is now much enlarged, hard, painful to the touch; epididymis is particularly affected. The whole organ has the form of a kidney, and is drawn upward; at times, when painful, the cord pulls the testicle up almost into the inguinal canal.

On palpation, an indefinite fluctuation is felt, like small cysts. After an examination, in which the organ has been handled, he always has an exacerbation of severe pain. There may be a slight amount of fluid in tunica vaginalis. Scrotum naturally a little stretched, to accommodate the enlarged testicle—is otherwise healthy. The left testicle is normal; there are no enlarged glands in inguinal regions. The cord is very hard, and has, to the touch, the appearance of a thick catgut, as tight as a string on a double bass. The beginning of the ailment was like an epididymitis. There is no syphilitic history. The symptoms exclude hernia and hydrocele. A positive diagnosis could not be made, but the symptoms are such to suspect carcinoma of the testicle.

Treatment relieved for a short time, but exacerbations followed soon after, so that in reality nothing was effected toward a cure. On the contrary, the patient got worse, with more severe pains and sleepless nights.

April 8th he was decidedly better, but on April 10th I found the scrotum enlarged to twice the size it had been at the former visit. The former state of the testicle was not altered, but an effusion of an uncertain character was added, resembling nearly a hernia. As nothing could be expected from treatment, extirpation of the organ was advised.

April 13th.—Operation in the presence and with the assistance of Drs. Rodenstein, Bryant, and Meier. No antiseptic precautions were used, except my usual habit to wash instruments and sponges used in a weak solution of carbolic acid. Ether was administered as an anæsthetic. Where the sudden effusion appeared, a small trocar was introduced, and three ounces of dark blood let out. Then a longitudinal incision was made in the anterior wall of the scrotum, and enlarged upward, in order to explore the cord. The tunica vaginalis was thickened, and contained more blood. Several small cysts, scattered about, were filled with a serous fluid. The testicle was enucleated, the cord tied high up in three parts with silk ligatures. Two vessels in scrotum had to be ligated. The wound was brought together with silver-wire sutures, and in the depending part a drainage-tube was inserted.

The rule as laid down in works of surgery, to separate the nerves of the cord, so as not to include it in the ligature, is a wise theory, but entirely impracticable. I never could trace these small nerves, and never have seen any ill effect from including it in the ligature. So in the present case the patient was free from any pain after the operation, and made a good recovery.

April 13th.—First dressing on the third day after operation. The wound had healed by first intention, except the place occupied by the drainage-tube.

On the fifth day half the silver-wire sutures and two ligatures were removed. On the seventh day the remaining wire sutures were cut out.

The strong ligature of the cord came away on the eighth, tenth, and seventeenth days.

May 9th.—Patient is well, walks about.

From the specimen you will see that the testicle has grown to a length of four inches; the epididymis is particularly enlarged and hardened. In the tunica vaginalis we find a large blood-clot with some gelatinous fluid intermingled; the membrane is so much stretched as to form a pouch like the cyst of a tumor. The tunica albuginea is thickened, and can be easily separated. The lobuli testis are rather softened, easily separated from each other, and emit to the touch a feeling of pultaceous matter. The arteries of the cord are enlarged, tough, and have a feeling as if atheromatous.

A satisfactory examination with the microscope, to ascertain the character of the neoplasm, has not been made, as the specimen has not hardened enough.

THE PRESIDENT asked Dr. Newman if he had searched carefully for the nerves in the cord.

DR. NEWMAN said that he had, and that in this case he was unable to detect anything which presented the appearance of nerve. In some cases he had seen possibly little fibres, but nothing destructive.

THE PRESIDENT said he inquired because a distinguished gentleman had proposed pressure upon the cord for neuralgia of the testis, and had claimed to have cured several cases in that manner, namely, by pressure upon the nerves. If, however, the nerves are not visible to the naked eye, perhaps the explanation was rather theoretical.

DR. NEWMAN also presented

SPECIMENS DISCHARGED FROM THE BOWELS,

with the following history:

Mrs. A. G——, aged twenty-six years; married three years; no children. Six years ago was kicked and trampled in abdomen by a man with heavy boots, which gave her pain and suffering for a long time.

April, 1881, the patient came under my care for membranous dysmenorrhœa.

June 21st.—There was a distinct tumor in left lumbar region, circumscribed, painful to the touch, but entirely disconnected with the uterus. It occupies a place, the boundaries of the transverse and descending colons; the same place which was injured six years ago by the heavy boots.

August 9th.—Patient in a letter states that two days ago she felt uneasy, and pain again in the left side. After some painful colic spasm, she felt something give way. Next morning a copious fluid was discharged from the uterus, after which she felt easier. (It is very doubtful that the discharge came from the uterus.) In October, 1881, menstruation appeared in regular time, but with pain, profuse

flooding, and the regular expulsion of membrane. Treatment was continued by dilatation of uterus, syringing cavity with carbolic acid solution, and application of Churchill's tincture of iodine.

The next month the menses appeared regular, without any pain or discharge of membrane.

Over four months she remained well. In March, 1882, she complained again of colic pains, and passing off of large pieces of membranes, which looked like the linings or pieces of membranes from intestines. Some of these pieces were preserved, and are the specimens presented here.

The interest in this case is the diagnosis, and this is the reason they are presented. The patient had membranous dysmenorrhœa, and was cured of it in due time. Simultaneously there was an independent tumor in the left side, which at times diminished and disappeared. The patient misled her physician by stating that the pieces had passed from the uterus, when in reality they were expelled by the alimentary canal. The question arose, whether the injury received six years ago had anything to do with the present ailment. The masses expelled could be only exfoliated parts of intestines, or foreign bodies. Dr. Peabody kindly examined the specimen microscopically, and reports as follows:

"March 27, 1882.

"Dear Doctor: The material in the bottle is without doubt food that has been bolted and subsequently passed, undigested. It contains many fragments of striped muscular fibre, much undigested connective tissue, and large masses of vegetable cells and fibres."

April.—The patient states that every other day she has severe pains, and the following morning those pieces came away. She remains under treatment. Her diet is very plain, and for weeks past she has not eaten any meat.

May.—Patient is decidedly improved, but passes still particles of the same nature from her bowels, off and on.

May 10th.—Saw her this morning, when she felt well in every respect, and no trace of the tumor is left.

EPITHELIOMA OF THE PENIS.

Dr. Willard Parker, Jr., presented a specimen, accompanied with the following history: A man, sixty-two years of age, with good family history, contracted a chancroid when twenty years of age. From that he recovered promptly under treatment, but has always had a spot upon the glans, which upon special exposure was peculiarly sensitive to irritation. Last December, soon after sexual intercourse, a point of tenderness developed upon the glans penis, which, although it did not present the appearance of a venereal sore, did not heal under treatment. The prepuce was exceedingly long, and although the sore seemed to improve somewhat, yet it never entirely healed. It was finally determined to administer ether, slit up the prepuce, and decide whether further operation should be performed or not, when the growth had been fully exposed to view. Accordingly, on April 3d, Dr. Hutchison, of Brooklyn, slit up the prepuce, found a large epitheliomatous growth, and removed the organ. The patient recovered from the operation rapidly and satisfactorily, and there remains a portion of the penis an inch and a half or two inches in length. The growth occupied almost the entire glans. It had been examined microscopically by Dr. Birdsall, who reported that it was typical epithelioma, nests of cells being present.

In looking up the literature of the subject, Dr. Parker found that Walsh had stated that out of between nine and ten thousand cases of cancer, he had found only ten of cancer of the penis, a degree of infrequency which to him was rather surprising.

Dr. J. C. Peters said that only a few cases had been published in the *Bulletin* of the Society, and he was surprised to find how rare the disease was and how difficult of diagnosis.

Dr. Carpenter had seen four specimens during the last year.

Dr. Liautard said it was a common affection among geldings.

PERITYPHLITIS—PERFORATION OF THE VERMIFORM APPENDIX BY A CHERRY-STONE.

Dr. F. Ferguson presented a specimen removed from the body of a young man, who was taken May 1, 1881, with violent pain in the right iliac region. He had been indiscreet in his general diet, and from the onset of the pain to within two or three days of his death had violent and persistent vomiting. His bowels had been frequently moved by medicine. On the ninth day of his sickness he came into the New York Hospital, and was described as being "cold and covered with a cold perspiration." His respiration was shallow, pulse feeble and rapid, and his face wore an anxious expression. Examination of the abdomen revealed a tumor extending from the right ileum upward to the extent of six inches, laterally four inches, exquisitely tender, and imparted to the touch a sensation of hardness and resistance on deep palpation. On the day following admission, the tumor disappeared, and there was an increase of the tympanites which existed when he entered the hospital, and a certain amount of resistance developed over the entire abdomen. The temperature on admission was 103° F., and it steadily increased until death, when it was $109\frac{4}{5}$° F.

The day before his sickness began, he ate freely of cherries, and was of the opinion that he had swallowed some of the stones. At the autopsy there were found considerable pus in the peritoneal cavity, recent lymph, and a large sac upon the right side filled with broken-down material. On close examination it was found that the wall of the ileum was extensively necrotic, the appendix vermiformis had been adherent to the side of the ileum, and the end of it was gangrenous, and in that region was a mass as large as a pea which was recognized as a cherry stone.

Dr. J. Lewis Smith presented a specimen of

INVAGINATION OF THE COLON,

for which he was indebted to Dr. Ewing. It was removed from the body of a negro girl, seven years of age, with the following history. Her parents were healthy, and she had been well until five months previous to her death, which occurred April 29, 1882. She first complained of abdominal pains, colicky in character, but not severe. These continued several weeks, increasing in frequency and severity, and Dr. Ewing was called in on March 13th. At that time, nor afterward, there was no marked febrile movement. During the interval between the colicky attacks she seemed to be healthy, although never entirely free from pain. Dr. Ewing had been led to suspect some displacement of the intestine, perhaps invagination. Dr. Smith saw the patient some four or five weeks before her death,

and they examined with reference to intussusception. There had, during the entire sickness, been diarrhœal evacuations from the bowels. They discovered no evidence of tumor.

There were also pains of a fugitive character in other parts of the body. There was not at any time marked vomiting. They were inclined to the opinion that she probably had intestinal catarrh with neuralgic pains. She gradually lost strength, stools of a thin brownish character continued, and death occurred from exhaustion. At the autopsy, a mass was found in the left side of the abdominal cavity measuring six or eight inches long, about three inches across, with a portion of small intestine protruding from it, and the caput coli with the ascending and transverse colon had disappeared. In the invagination were the head of the colon, the ascending and transverse portions and a part of the ileum. Dr. Smith thought it began by prolapse of the lower part of ileum, through the ileo-cæcal valve, dragging after it the caput coli, and then the colon. It was probably one of those cases which could have been relieved in the early stage, could diagnosis have been made, either by distention with gas or water or by laparotomy. Probably it existed two or three months before death, perhaps five months. The small intestine was excessively hyperæmic throughout its extent up to within ten inches of the invagination, and Dr. Smith thought the intense congestion was due to inflammation.

On a previous occasion he had studied the statistics of the subject, and noticed the fact that with intussusception occurring after two and one-half years of age there was some antecedent disease or condition that would be likely to cause disturbed action of the intestines, such as diarrhœa or constipation. It might be that the evidence of ileitis antedated the occurrence of the displacement.

Dr. F. V. White asked Dr. Smith which he had found most effectual in the treatment of invagination, gas or water?

Dr. Smith replied that he had been more successful with water than with gas or air.

Dr. Janeway remarked that it was difficult to decide how long an invagination had existed, or just how much occurred immediately preceding death. Perhaps by section of the specimen something might be found which would assist in explaining the condition, as, for example, an intestinal polypus. Periodicity in the occurrence of pains was a feature of these, as well as many other cases, without any influence whatever from malaria.

Dr. White referred to a case of invagination successfully treated by his father many years ago, by introducing the nozzle of a common pair of bellows into the rectum and distending the intestines with air.

PERICARDITIS ("HAIRY HEART") — FIBRO-PURULENT EXUDATION BETWEEN THE LEFT LUNG AND DIAPHRAGM — INTERSTITIAL NEPHRITIS WITHOUT ALBUMEN IN THE URINE—DEATH FROM URÆMIA.

Dr. B. Robinson presented the heart which illustrated the above lesion. The history of the case was furnished by Dr. W. C. Campbell, House Physician at St. Luke's Hospital. Chas. W. M——, seventy years of age, was brought to the hospital, April 15th, suffering from intense pain in the left lumbar region, intense dyspnœa, and slight cough without expectoration. Respiration 28, and shallow; pulse and temperature normal. Pleuritic friction sounds over the whole of the right side of the chest. Patient passed no urine during the night, and on the following morning well-marked symptoms of uræmia were developed. The catheter was introduced and twelve ounces of urine drawn, which had a specific gravity of 1025, acid, contained *no* albumen, but granular casts in abundance. He died in profound coma at 9 P.M.

At the autopsy, the right lung was found firmly bound down by old adhesions, and there was well-marked evidence of bronchitis and hypostatic congestion. The left lung had no adhesions except at the base, where there was a thick fibro-purulent exudation connecting it with the diaphragm. There was fibrous induration at the apex and the whole lung was the seat of hypostatic congestion.

The heart presented the lesions of pericarditis.

The kidneys were granular, deeply congested, and plainly were the seat of old interstitial nephritis.

An interesting point in the clinical history of the case was the occurrence of intense dyspnœa associated with symptoms of uræmic poisoning, and yet there was no albumen in the urine drawn from the bladder. Dr. Robinson thought that, in view of the condition of the kidneys, the dyspnœa was not due to the pleurisy, but was rather of the respiratory form described by Fournier, as occurring in cases of interstitial nephritis.

Dr. Robinson also presented a specimen illustrating well-marked

AORTIC AND MITRAL STENOSIS.

Chas. H. F——, fifty-two years of age, married, seaman, and for the last ten years a merchant. Family history of rheumatism, and father died of cardiac following frequent attacks. Thirty-five years ago the patient had a chancre and other symptoms of syphilis, but there have been no manifestations of the disease since. His habits were regular and temperate, and he was unusually strong and athletic. He had his first intimation of cardiac disease about thirty years ago, when palpitation developed after violent exertion or under excitement, and this occurred soon after a very severe strain in endeavoring to save himself while falling from the masthead. Ten years ago he had his first and only attack of acute articular rheumatism, the knees and ankles being affected. Six years ago palpitation became a more prominent symptom, and he gradually lost flesh and strength. Five weeks before admission he began to cough considerably, and had marked dyspnœa.

On admission he complained of frequent attacks of palpitation and intense dyspnœa, slight cough, nervous prostration, and dyspeptic symptoms. There were no central symptoms. The urine was somewhat diminished in quantity, specific gravity 1026, acid, and heavily loaded with urates and oxalate of lime.

On physical examination by Dr. Robinson, a blowing murmur was heard at the apex, in the axilla, but not behind, and with greatest intensity to the right of the left nipple, decreasing in intensity as the ear was carried upward, and finally disappearing at about the middle of the sternum. A similar murmur was heard at the base, most distinctly at the *second* intercostal space and to the right of the sternum, and propagated into the great vessels. Pulse small and compressible. No marked œdema, but intense dyspnœa. Diagnosis: aortic and mitral stenosis, with both heart-cavities enlarged. The dyspnœa was relieved temporarily by the administration of small doses of morphia hypodermically, and the

inhalation of oxygen. He died from sudden failure of heart-power, April 15th.

At the autopsy considerable fluid was found in both pleural cavities, hypostatic congestion of the lungs, adhesions at the right apex.

The heart weighed one pound and fifteen ounces. Both ventricles were greatly dilated. The wall of the left ventricle was extensively hypertrophied, that of the right thin. The aortic valves were bound together firmly and calcified; the orifice was markedly contracted. The flaps of the mitral valve were thickened, and showed some spots of ulceration. The orifice was slightly narrowed.

The kidneys and liver were congested. The specimen was interesting, because it exhibited lesions which explained the physical signs. At the same time it might be added that frequently similar pathological lesions were found associated with other clinical phenomena. For example, in a given case a murmur was heard that indicated mitral regurgitation, and after death there was stenosis, rather the condition that ordinarily gives rise to mitral insufficiency. To argue from the murmurs heard as to what pathological lesions would be found, was, in Dr. Robinson's opinion, to a certain extent a mistake.

Dr. Janeway remarked that the question of uræmic dyspnœa was one in which he had been much interested, and he had seen many cases in which severe dyspnœa existed without either cardiac or pulmonary disease to explain it. His rule was to invariably examine the urine in all cases of dyspnœa, and especially should it be done when dyspnœa occurred without disease of the heart or lungs. The first symptom of Bright's disease not infrequently was an attack of dyspnœa, and the case might require active and prompt treatment. In these cases Cheyne-Stokes respiration was frequently present. With regard to the specimen of mitral stenosis, it seemed to him to be important to distinguish between thickening of the mitral valves and pure mitral stenosis. When he could introduce two fingers, as in the specimen, he did not like to call it pure stenosis, but rather thickening of the mitral valves.

Again, the mitral leaflet might float up and give rise to presystolic murmur, which did not imply mitral stenosis, and it was difficult to judge as to which condition the murmur was due. This occurred not infrequently with mitral regurgitation.

NECROSIS OF THE SPINOUS PROCESSES OF THE VERTEBRÆ.

Dr. J. A. Wyeth presented the remains of three spinous processes, namely, the last cervical and the first and third dorsal vertebræ, removed on account of necrosis. There was an immense abscess, which was opened, and after the man had recovered from that somewhat, it was laid open throughout its entire extent, and necrosis of the spinous processes found. The diseased portion was removed, and the patient made a good recovery. The specimens were interesting, as illustrating necrosis of the spinous processes *without* disease of any other part of the vertebræ.

Dr. Wyeth also presented

A PIECE OF SILK THREAD WITH WHICH HE HAD LIGATED THE EXTERNAL PLANTAR ARTERY IN SYME'S AMPUTATION.

The operation wound was closed with carbolized sutures, united by first intention, and within two months the patient began to wear an artificial foot. He did well for five months, when an abscess formed and within two or three weeks the piece of ligature with which the artery had been secured appeared. Dr. Wyeth also referred to a case of ovariotomy in which thin abscesses formed some time after the operation, and finally the silk ligatures were discharged.

Dr. E. G. Janeway presented a specimen of

CYLINDRICAL EPITHELIOMA OF THE CÆCUM, WITH SECONDARY NODULES IN THE LIVER, OMENTUM, UTERUS, AND RIGHT LUNG.

They were removed from the body of a woman, sixty-six years of age, without history of cancerous disease, and who had always been healthy until four years before her death. For two years she had simply a feeling of fulness or distention in the side. During the last two years she had periodical attacks of vomiting, the material vomited sometimes being black and offensive. These attacks occurred at first at intervals of a month or six weeks, and finally as often as every week, and the periodicity was very marked. There was gradual loss of flesh and strength, a certain amount of pain along the course of the nerves, and the patient finally died of exhaustion.

During life the area of hepatic dulness over the right lobe was increased downward, but it was somewhat difficult to say whether or not the liver was enlarged, especially as the patient was a woman. In the ileo-cæcal region there was a certain amount of induration, nodular in character, and ileo-cæcal obstruction was diagnosticated, but beyond that it could only be said that it was probably cancerous in character. As to whether the origin was primarily cancerous or typhilitic degenerating into cancer, was difficult to say.

At the autopsy there was found entire absence of any projection of the large intestine below the entrance of the ileum. The ileum entered the large intestine at a place where it was about an inch in diameter, with very thickened walls, in the condition of carcinoma. The surface at that point was ulcerated, but there was no mucous membrane. It could be seen that there had been retraction by ulceration and loss of cæcal protrusion. Moreover, there was no appearance of true ileo-cæcal valve. There was a thrombus in the external iliac vein.

Strung along the omentum throughout its length were nodules of new growth, varying in size from an inch and a half to half an inch in diameter, firm and irregularly rounded, and they were separated from the lower border of the large intestine. They could have been very easily mistaken, during life, for scybalæ in the large intestine, both from feel and position.

The liver presented a projecting right lobe, which was described as it appeared during life, projecting a little more than two inches below the free border of the ribs. There was no new growth in this portion except above and behind where it joined the main portion of the right lobe, and there it was the seat of carcinomatous infiltration. The remaining portion of the liver was the site of numerous nodules of new growth, varying in size from a pea to two inches in diameter. The largest nodules were umbilicated and free upon the surface. In the lower lobe of the right lung was a spot of new growth, surrounded by a certain amount of inflammatory change. The remaining portion of the lungs were somewhat œdematous.

The uterus showed a growth somewhat irregu-

larly rounded, *two* inches in diameter, and occupying the position of the posterior lip, and implicating the posterior wall of the vagina. This was only slightly eroded on its vaginal surface. It was probably of rapid growth, as the patient was examined three months before death, by a competent gynecologist, who said there was no evidence of uterine disease.

The point of interest in the specimens was the appearance of secondary cancer in places where primary cancer usually occurs. By some it has been regarded as absolutely the rule, by others nearly so, that secondary cancer does not occur in such places as are usually the site of primary carcinoma. But this was the second exception which Dr. Janeway had seen of recent date. The other case was one of carcinoma of the left breast, secondary to primary cancer of the left lung. The diagnosis was made eight months before death, and examination of the breast from time to time, finally resulted in the discovery of a small nodule, *two* months before death, and the autopsy revealed carcinoma of the left lung and breast, and also of the right lung and liver.

In this case, as in some others he had seen, the appearance of the carcinoma of the lung was such as might readily lead one who does not make a microscopical examination, to regard the disease as chronic pneumonic infiltration.

Again, with reference to the diagnosis between the downward projection of the right lobe of the liver and a movable kidney, the liver moves upward and downward in respiration, while the kidney does not. The kidney can be pushed from behind forward on an axis formed by its vessels, and can be pushed back into the lumbar region with a kind of jump which can be appreciated by the hand.

In answer to a question from the president, Dr. Janeway also directed attention to resonance upon percussion intervening between the lower border of the liver and the upper border of the kidney.

On microscopical examination the new growth in the omentum, neck of the uterus, liver, and the lung, as well as the tumor at the primary seat of the disease, the cæcum, all had the structure of epithelioma of the cylindrical type.

The Society then went into executive session.

CAROBA.—In Brazil an infusion of the leaves of the caroba (*jacaranda procera*, Sprengel) as well as Dr. Colmeiro's electuary are much used in the treatment of cutaneous and syphilitic affections. The infusion is made of 1 part of the leaves to 9 parts of water. Dose, ʒ i. t. i.d. The formula for the electuary is as follows:

Powdered caroba leaves	45 parts.
Powdered sarsaparilla root	15 "
Senna leaves	15 "
Calomel	1 part.
Syrup	q. s.

Dose, ʒ i. bis ind.

Caroba contains an alkaloid (carobine) crystallizing in silky needles, insoluble in ether, and rapidly soluble in water and boiling alcohol; two acids, one (carobic) crystallizable in stellate forms and soluble in water and alcohol, and another (stero-carobic) of pale brown color; a resin (carobone), amorphous, balsamic, and acid; a balsam of syrupy consistency and agreeable aromatic odor, and other less important principles.—*El Sentido Cat.*

Correspondence.

EXCISION OF THE INTESTINAL CANAL WHERE COVERED WITH PERITONEUM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—In the number of THE RECORD for June 17th, in the report of the transactions of the Surgical Section of the American Medical Association, I am credited with conclusions upon excision of portions of the alimentary canal that were quoted from Koeberlé. I fully endorse his conclusions, and had put them in practice years before he published them, and published an illustrative case in the *Philadelphia Medical and Surgical Reporter*, of October 25, 1879. The conclusions I drew from my own and other cases are as follows:

First.—Any portion of the alimentary canal may be safely excised, and stricture, cancer, perforating ulcer, and gangrene demand that it shall be done.

Second.—The method heretofore adopted of suturing the divided ends of the bowel is dangerous, because tympanites, by pressing upon the heart and lungs, interferes with the vital processes in a patient already worn down by disease and shock, and by distention causes traction upon the sutures in such degree as, in many instances, to cause their giving way, which is followed by fecal extravasation, peritonitis, and death.

Third.—These dangers are to a great extent obviated by making an artificial anus, and permitting the escape of the gases as they form.

Fourth.—Artificial anus is easily cured by a plastic operation devised by myself, and described in the paper.

Fifth.—If that portion of the bowel which constitutes the eperon be cut away at the time of the first operation, no suture operation will be found necessary, as the artificial anus will close spontaneously by cicatricial contraction.

Sixth.—The successful cases reported in the paper prove the propositions to be true.

To the conditions requiring excision I should have added "some gunshot wounds."

In the discussion that followed, Dr. Ransohoff suggested that the cutting away of the eperon at the first operation might be unadvisable on account of it consisting of the mesenteric portion through which the bowel receives its nutrition. His objection is good, and valid to some extent. The vascular supply is so great, and the anastomoses of the blood-vessels in the intestines so extensive, that it is very probable that sufficient nutrition would be carried to exposed parts, and it is further well known that vessels are rapidly thrown out from adjacent parts that supply nutrition, as happens to the distal portion of the pedicle where it is tied and dropped in ovariotomy operations. Still, such an objection may be shunned by a quarter-turn of the intestine, and excision of a portion that would be eperon to one side of the mesenteric attachment.

In the paper I collected all the cases of excision of the intestine, for whatever cause, that I could find a report of, and in several I found that the patients that had been operated upon died from the giving way of the stitches within the abdomen. This could have been obviated by making an artificial anus. There is still another danger that will not be en-

countered by following the same practice, and that is the cracking open of the peritoneal coat of the bowel from overdistention. From these crevices exude inflammatory products that, decomposing within the abdomen, produce the septicæmia and death as described and insisted upon by Drs. Dugas, Sims, Hunter, McGuire, Peaslee, W. T. Briggs, and others. The overdistention causing, in many cases that are already worn down, paralysis and consequent intestinal obstruction, a condition that undoubtedly kills many patients who have typhoid fever. I have seen, in one case of typhoid fever that I was called to several years since, with Dr. Francis Drude, of this city, where there was enormous tympanites the most markedly favorable result from aspiration removing the excessive gases. These gases are prone to accumulate after all serious abdominal operations and the accumulation is one of the almost constant complications of ovariotomy.

The closing of the intestine and dropping it back into the abdomen, and stitching up of the abdominal wound, prevents ready drainage and removal of the septic products of inflammation. When an inflammatory process elsewhere than in the abdomen produces pus or other septic material, the first thing the surgeon does is to make large openings and give it free exit, and, if he considers it necessary, he goes farther and washes it out with some antiseptic solution. This treatment of late has been adopted even in the treatment of joint diseases, a class of cases that were approached a few years ago with as much fear as the abdomen was; no one will deny that the present practice is not superior to that of the past, then, things equal to the same thing being equal to each other, why not apply it to all conditions where there is retained septic material, not waiting until there has been poison enough absorbed to overpower the patient, for such waiting would be disastrous alike to the good fame of the surgeon and the profession. Neither would I have it supposed that I favor indiscriminate abdominal and intestinal section, but I would have it made in those cases that have heretofore proved so fatal.

This doctrine is not new with me, as will be seen by referring to a paper read by myself at the meeting of the American Medical Association in Richmond last year. Some of the gentlemen in discussing the paper seemed to forget that it referred to any class of excisions except in cases of gangrene from strangulated hernia, or, what is more probable, did not hear the paper read, and discussed it from the hearsay standpoint. These gentlemen, who are able and conscientious surgeons, that are teaching and teaching well the science and art to those that are to come after us, opposed any interference in cases of gangrene in strangulated hernia further than simple incision, holding well to the doctrine taught in the text books, "not to meddle with the adhesions." Now, this doctrine, I think, will admit of considerable modification.

There are cases where, as in femoral hernia, the opening under Poupart's ligament leaves a very narrow contracted opening, that is likely to become much narrower, and if spontaneous cure of the artificial anus ensues, there is a liability to partial or complete intestinal stricture that may at any time become blocked by solid or semisolid egesta. The same objection will apply to gangrenous hernia occurring anywhere else, where half, or more, not including the whole, diameter of the intestine becomes gangrenous. The very fact of spontaneous cures of artificial anus occurring renders the risk greater than if the opening has been cured by the surgeon cutting down the eperon with an eterotome or other means, ensuring a sufficient passage-way for the contents of the bowel.

The fear of being unable to close the artificial anus I believe has deterred surgeons from making it as often as they would otherwise have done, the operation I have introduced and described, both in the paper read at St. Paul and in the *Philadelphia Medical and Surgical Reporter*, of October 25, 1879, I hope will be as efficacious in other hands as it has been in mine, though I hope the cutting down of the eperon at the first operation may take the place of any plastic secondary operation.

My own experience has been limited, having performed enterotomy and making artificial anus but six times, of that number none died under two months, none died from the operations or its consequences; three are yet living, and of the three one had eight inches of intestine and a large piece of omentum excised October 9, 1878, and one had three inches of intestine excised January 21, 1882, both are in excellent health and bid fair to be for many a day. I hope that other and abler men, men who have better opportunities to investigate, and whose reputations bring them more patients, will investigate this subject thoroughly and impartially, that the truth may be arrived at. That one man, very able to render great service has commenced the work, I am informed through the columns of the London *Lancet*, and *British Medical Journal*. That man is Mr. Thomas Bryant, of Guy's Hospital. He reports a successful case of excision of a stricture in the descending colon, leaving an artificial anus. In conversation with him, last August, I entered minutely into the subject and sent him the papers I had written. Hoping that my own countrymen may assist in the rapid and correct solution of these problems,

I remain, very truly yours,

WILLIAM A. BYRD.

407 JERSEY STREET, QUINCY, ILLINOIS, July 17, 1882.

WHAT IS A CONSULTATION?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—The question has arisen in the mind of the writer, who is as yet but little experienced as to the practical working of codes of medical ethics, as to what constitutes a "consultation." Is it a consultation for a specialist to treat a patient sent to him by a physician of another school? An oculist, for instance, prescribing treatment, can hardly be said to consult with the general practitioner who has given the case over to his direction. His authority becomes supreme, and whatever he may recommend is followed implicitly and naturally because of the existence of confidence in his great skill on the part of those who have employed him. He does not compromise himself in any way as regards professional integrity, he yields no point as to the treatment to be pursued. On the other hand the general practitioner, who has given the case up to his direction, no longer has any responsibility as regards the treatment, that having been decided upon by the specialist. The only question that remains is as to whether it is justifiable to treat a patient knowing that he will employ a physician of another school to act in a subordinate capacity—really as a nurse—whose business is simply to see that the treatment prescribed is properly carried out? With

this view of the case, is it a matter worth contending about?

Again, suppose a family employing a homœopathic physician wishes to obtain the opinion of a physician of the regular school, is it a "consultation" for such a physician to respond and to express himself as freely as he pleases in regard to the case in question and the treatment to be followed? Is it not rather a grand opportunity for him to vindicate the honor of the profession by demonstrating practically that he is possessed of superior judgment and skill. If the parties who have called him are convinced that he has a better understanding of the case and yield to his judgment, it is an evident victory; and in any case there is no longer room for the lurking suspicion or the open taunt, that the doctor is afraid to meet the homœopath. He has not yielded one iota of his principles or convictions. If he finds the homœopath giving such medicines as are prescribed by the regular school, he has fine opportunity to call attention to the fact, and thus destroy at a blow the false pretensions that have existed; or, if he finds quackery rampant, he can refuse to have anything further to do with the case unless the treatment he may recommend is adopted. In any case, it does not appear that he has had a consultation or sought to have had an agreement with a heterodox practitioner. On the contrary, he has done his duty to suffering humanity, and taken the surest means to uproot quackery. It seems to the writer that if physicians have the privilege of doing the things indicated, it is all that can be asked or expected, and that any talk about freedom of consultation beyond what has been indicated is rather nonsensical from any point of view. In fact, the discussion that has arisen about the modification of the code appears to be having the undesirable effect of giving quackery the benefit of a vast amount of free advertising, whilst it appears that the point at issue is exceedingly small, provided that practitioners are allowed to do what has been indicated in this article.

LYONS, N. Y., July, 1882.

SUPPOSED DEATH BY CHLOROFORM.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR—It is desirable that there should be recorded every death attributable to the anæsthetic agents in use, for it has hardly been settled that one of these agents should be universally employed because of its immunity from danger. In certain sections of our country, and of Europe, chloroform is still the favorite article used, for its general adaptability, and because, in the largest experience, it has proved safe and satisfactory. In other sections there is a strong prejudice against chloroform, and a belief that ether is entirely free from danger. I have, in an experience of more than thirty years, never had occasion to distrust chloroform, and have never until now seen a death attributable to its administration. From very many experiments and observations, I have, however, been led to the belief that ether is less apt to be followed by nausea or by great depression of vital power. My rule of practice, then, in late years, has been to employ chloroform as a rule in surgical and obstetrical practice, except in operations necessarily protracted, or where nausea or vomiting would be prejudicial to the condition of the patient. I am inclined to doubt whether the death in the case which follows can be attributed solely to chloroform. Fright, terrible anxiety, a peculiar nervous organization, and an exalted moral sensibility, may have had much to do with the sad termination. But I prefer reporting the case and leaving it to the verdict of the profession. Further interest attaches to it from the fact that a vile secular press has circulated through the country the grossest misstatements regarding the case itself and the conduct of the physicians connected with it. I will notice and correct only two of these. It has been falsely stated that my assistants were introduced into the operating chamber of the patient against her wishes and while she was insensible from chloroform. The truth is, that the consent of the lady was freely given, because she knew that assistants were necessary. Her only desire was that she should be chloroformed before the assistants were introduced. Next, it has been affirmed that the cause of death was suppressed to shield the physicians and to prevent a coroner's inquest. The truth is that the death (although the matter was rather doubtful) was at once assigned to the chloroform, and this fact frankly announced to the family of the deceased and to others. Moreover a mortuary certificate of death from "*Chloroform Narcosis*" was handed to the City Registrar in order to obtain a permit for burial.

CASE.—On May 7, 1882, I was called to attend Mrs. L. R——, who had long been an invalid, and who had been attended before by two very worthy practitioners of this city. She was forty years of age, married, and the mother of two children, the last being six years old. I found her thin, anæmic, and unable to exercise without much backache, never sleeping well at night, having usually prolonged and profuse menstruation, in the intervals much leucorrhœal discharge, bearing-down sensations, with vesical and rectal tenesmus, difficult digestion, and constipation. These symptoms had in part pertained to her since the birth of her first child, but had been more continuous and severe for several months past. There was now also severe paroxysmal cough, with the physical signs of subacute bronchitis on both sides of the chest. The pulmonary symptoms Mrs. R. attributed to a recent cold, and said she had sent for me chiefly to relieve her of the trouble which she had had during many years, and which made life a burden to her. She said she knew her disease to be uterine. Other physicians had treated her for this, but she was in hopes that a radical operation might entirely relieve her. There was prevailing an epidemic of whooping-cough, and the children in the house had suffered. Mrs. R. had formerly had this disease, but the character of her pulmonary symptoms led me to believe that she was to some extent suffering from the "epidemic constitution of the atmosphere." She was anxious for a thorough examination, so, after prescribing for the cough, I appointed an early day for the purpose. In due time I discovered a left lateral fissure of the cervix, reaching to the cervico-vaginal junction. Also an elongated and enlarged cervix. A prolapse of the bladder, and prolapse and partial retroversion of the uterus. I gave as my opinion that much could be done by treatment, both local and general, but that first of all the cough must be relieved, and the digestive organs improved. In time I proposed to apply local remedies to the uterine and cervical cavities, and to close the fissure by operation. Mrs. R. was intent upon an early operation, as she said she had too long been trying palliative remedies. I could with difficulty persuade her that these

medical means must for a time be postponed. After about a month's general treatment, part of which time I was absent from the city, Mrs. R. had so improved that she again renewed the question of operation, saying that the cough did not now affect her, and that she wanted to be attended to before leaving the city for a summer's vacation. While regarding her as rather a bad subject for operation, I nevertheless thought the cervical fissure could be closed without risk, and that by the use of a pessary she could be enabled to go comfortably into the country.

June 19th was appointed for the operation. Mrs. R—— had always been sensitive as to the matter of personal exposure, so I readily assented to give the chloroform only in the presence of female attendants. When the request was made for patient to get upon the table, she became very much excited, and could scarcely be comforted and assured. She shrank back as one having a feeling of impending danger. I subsequently learned that she had had a presentiment of danger, and went so far the night before as to write out requests she wished fulfilled after death. I mention these facts to illustrate the nervous condition of the patient, as with many it may be considered as having something to do with her sad end. The chloroform was given upon a towel folded funnel fashion. The towel was first held a little distance from the face until the patient grew accustomed to the vapor, and habituated to the proper inhalation. The usual period of excitement came on, with some struggling of the arms and rolling of the body. One of the female attendants helped to control these movements, and in a short time relaxation began to be evident, with the slightest stertor of breathing. Less than three drachms of chloroform had been used. I at once suspended the chloroform, passed the towel over to the nurse, who was at the bedside and a little removed, and told her to hold it where she was. I felt no apprehension about the patient, and moved to the door separating the chamber from the parlor, and called to Drs. Simons and Pelzer, my assistants, to enter. I now took my position at the foot of the table, while my assistants remained at the side, and began to put the patient into the semi-prone and lateral position for operation. I little thought that during the few seconds of my absence the cumulative effects of the drug would be exhibited. Glancing at the face of the patient I suddenly discovered that it was cyanozed, and the eyes staring and fixed. I called to Dr. Simons to notice if the breathing was right, and almost simultaneously we both advanced to patient's head. I saw that the respiration was embarrassed, and heard a gurgling noise coming from the presence of mucus secretion in the bronchi. Dr. Simons raised the head of patient and turned her body partly over into the supine position. I threw up the windows, dashed cold water upon the face and chest, slapped the surface smartly, depressed head while body and lower extremities were raised; injected brandy, and, subsequently, liquor ammonia and brandy subcutaneously, wrung towels out of very hot water and applied them over cardiac region; galvanic battery was used as soon as this could be secured, and finally, noticing that the respiratory movements were now entirely arrested, and also the heart's action, while the veins in the neck were greatly distended, I opened, first a vein at the bend of the arm, and subsequently the external jugular on the right side of the neck. I hoped that by removing some of the dark blood from the cavities of the heart, this organ would have a better chance for contracting. All to no purpose. The heart remained paralyzed, and we had soon to realize the fearful fact that death had occurred.

Respectfully,

R. A. KINLOCH, M.D.

CHARLESTON, July 18, 1882.

RELATIONS OF COUNTY TO STATE SOCIETIES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: If a county medical society repudiates the action of the State Society in the matter of the new code, in what way will such action affect the relations of the County Society to the State Society?

Yours respectfully, INQUIRER.

[The County Societies have a perfect right to express their opinion on the question of the code in any way that they see fit without affecting their relations to the State Society; they must, however, formally adopt the new code as one of their by-laws if they desire to retain their legal status and corporate rights as a County Society, and their right to be represented in the State Society. The medical act of April 7, 1866, gives the State Society supervision over the by-laws of the County Societies; in fact they do not become legal by-laws until they receive the sanction of the State Society, and, of course, a society without by-laws that can be enforced is a sham. For instance, if a County Society declined to accept the new code and adhered to the American code, and if in that county, charges were brought against a member for violating their code, the member if expelled would, if he appealed to the courts, be immediately reinstated as a member. The only way in which a body of physicians now constituting a County Society, can release themselves from obedience to the authority of the State Society is by giving up their chartered rights, and their present legal title and forming a voluntary non-incorporated association. In that case they could enact such rules, ethical or otherwise, as pleased them. If this course should be pursued, some other body of physicians of a different mind could meet together, as provided by the act of 1806, organize as a County Society, assume the title of the old society, adopt by-laws in harmony with those of the State Society, and be entitled to representation in it. They would in fact become the regular County Society.—ED.]

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 23, 1882, to July 29, 1882.

ELBREY, F. W., Capt. and Asst. Surgeon. Granted leave of absence for six months on surgeon's certificate of disability. S. O. 168, A. G. O., July 21, 1882.

RAYMOND, H. I., 1st Lieut. and Asst. Surgeon, to proceed at once, with necessary attendants from Whipple Bks. via Ft. Verde, to the scene of recent engagements with hostile Indians near General's Spring, and bring in those wounded to Fort Verde, and remain in charge of post hospital there until further orders. S. O. 112, Dept. of Arizona, July 19, 1882.

CARVALHO, CARLOS, Capt. and Asst. Surgeon. Died near Boston, Mass., July 23, 1882.

A New Medical School in Australia has just been established. The school is a part of the Sydney University and is well endowed by Government.

Oxydized Water will, according to Mr. Paul Bert, arrest fermentation from organized ferments, but has no effect upon unorganized ferments.

Comparative Size of Drops.—The following table approximately gives the average number of drops in a *fluid drachm* of the various classes of U. S. P. preparations:

Sulphuric ether	174	Mixtures	89
Fluid extracts	141	Vinegars	77
Spirits	141	Syrup not containing fl. ext's.	69
Tinctures	136	Solutions (1 exception)	66
Volatile oils	131	Diluted acids	61
Oleo-resins	124	EXCEPTIONS:	
Acids (3 exceptions)	123	Sol. nitrate of mercury	131
Wines	106	Nitromuriatic acid	76
Fixed oils	103	Muriatic acid	70
Syrups containing fl'd xt.	97	Sulphurous acid	59

M. Pasteur is a native of the Jura, President Grévy's department, and is short, angular, powerfully built, and shows in his countenance his humble origin. One sees that he has issued from a hard-working race, and has himself led a laborious life. People who have leisure are wordy and take time to give neat and graceful turns to their phraseology. This is seen in M. Renan. M. Pasteur goes straight to the point. He speaks in a clear voice, is a close reasoner, emphasizes to make his hearers well retain what he says, and not to charm their ears, and uses abrupt, quick gestures, which, if not elegant, are telling. Pasteur is a steadfast believer in Spiritualism. He was not ashamed to say that in his estimation there was nothing positive in the Positivist doctrines of Comte. The central fact of the universe, namely, Infinity, was, he continued, overlooked by the Positivists, whose forecasts, political and social, time had shown to be wrong. They were only in the truth when they accepted the conclusion of Littré, to the effect that, without a spiritual link, the human family would fall to pieces and nations become as mere hordes. But they fell into the error of placing this bond in a sort of religion, proceeding from humanity, and inferior to it.

Dissection Material.—About six hundred bodies are dissected annually in Berlin.

The Deaths from Intemperance in Great Britain and Ireland number annually about forty thousand, according to Dr. Norman Kerr.

An Institution for the Application of Euthanasia.—A singular legacy was recently left to the French Government by M. Giffard, the well-known Parisian inventor of balloons. He desires that his money shall be devoted to the establishment of national institutions, in which persons suffering from painful and incurable diseases may be allowed, by the use of chloroform and other anæsthetics, to put an end to themselves, under the direction of medical experts, and with the consent of their friends. M. Giffard, it is said, secured an euthanasia for himself by means of a special apparatus he invented for the inhalation of chloroform. M. Renaud is reported to be in favor of painless suicides in such cases, his only stipulation being that no man shall by law be entitled to take his own life until he has obtained the consent of his friends in a *conseil de famille*.

War on Pasteur.—A correspondent of the *Cincinnati Lancet and Clinic* has visited the laboratory of the Brown Institute near London, and describes the experiments which Klein is making with anthrax vacilli. He finds that these vacilli multiply by spores at 40° C., but do not do so at 43° C. This agrees with Pasteur's experiments. Klein finds, however, that the cultivation of the vacilli can be done without spores (by fission) at 25° C. The cultivated vacilli, however, had no protective influence upon rats, guinea-pigs, mice, etc., as averred by Pasteur. It seems probable that further experiments will fail to confirm some of Pasteur's conclusions, and we are informed that there is likely to be war to the knife.

Yale Thermometric Bureau.—The report of Mr. Waldo for 1881–82 states that 3,811 physicians' thermometers have been examined in the year 1881–82, which is more than double the number of the previous year. Four were broken at the observatory in handling and twenty in transit, the latter being in all cases carelessly packed. The amount of error found in the readings averaged about 1° F.

The Second Year Course of Anatomy has been abolished by the College of Surgeons of England. Students are now obliged to attend anatomical lectures for one year only.

Medical Æsthetics.—At the banquet given at the annual meeting of the State Medical Society of Arkansas, there were ingenious accompaniments to the feast. At each plate was a little white roll, in appearance suggesting a surgeon's bandage and labeled "Epicurean bandage." Upon unrolling this it was found to consist of a yard of fine gros grain silk ribbon, upon the middle third of which was printed, in red letters, the bill of fare, in the form of a prescription, in Latin phraseology, the perusal of which afforded much amusement. At each plate also lay a model of a surgeon's saw in stiff card, upon which were printed the toasts, with the names of those who were to respond to them.

Baronetcies and the Medical Profession.—English doctors are vexed just now that nine baronetcies have recently been conferred and none given to doctors. The *Medical Press and Circular* gives the comforting intelligence that one was conferred upon a Mr. Lawes—an estimable gentleman who deals in manure.

Acne Filaris and Acne of the Face.—M. Lallier, of the Skin Hospital (St. Louis), thus treats acne filaris, which develops itself on the forehead, near the hair, slightly resembling eczema:—1st. The following lotion to be applied every night: Sulphur (flowers), ʒ vj.; alcohol, ʒ iss.; water, ʒ j.

2d. Alkaline baths. 3d. Take at each meal half a teaspoonful of bicarbonate of soda in a little sugared water. As to acne of the face, he applies every night, with a hair pencil, the following preparation: Water, ℥ iv.; camphorated spirits, ℥ j.; washed sulphur, ℥ ss.; glycerine, ℥ iiss.; which is carefully washed off in the morning. When sulphur does not succeed in the treatment of acne, recourse may be had to black soap, which can be employed for four consecutive days, after which abstention is enjoined, when the treatment can be recommenced; and so on until the patient is cured. But as the general health generally requires looking after, M. Lallier orders tartrate of iron, ℥ ss.; aloes, eight grains, for 100 pills; two to be taken at each repast.

Phenic Acid in Whooping-cough.—Dr. Aymerich recommends, in the treatment of whooping-cough, the employment of phenic acid with bromide of potassium: bromide of potassium, ℥ j.; phenic acid, three to four grains; syrup of lemons, q. s.; vehicle, ℥ vj. A large or a small spoonful, according to the age of the patient, every two hours. He has never seen any accident to follow from the antiseptic agent.—*Medical Press and Circular.*

German Ovariotomy.—Professor Schroeder (Berlin) has performed two hundred and fifty ovariotomies. The first hundred gave a mortality of seventeen, second of eight, and only three died of the last fifty operations, of these only one of septic infection. Schroeder sees no reason why he should abandon his style of operation. He retains the spray, as he asserts that the peritoneum absorbs the germs of infection, and it was impossible to clean all its parts in such an extent by any other method. Besides this, he is no great friend of a large assortment of instruments and of too many assistants. He does not believe that he could decrease the mortality to a much lower degree than he had obtained, averaging five to fifteen percentage. Martin's percentage of death is eighteen, and he only differentiates from the former operator by operating between the legs of the patient whilst sitting.—*Berlin Klin. Wochensch.*

Strangulated Hernia Treated by Belladonna.—Mr. Smith Batten (*British Medical Journal*, July 15, 1882) reports two cases of strangulated hernia treated successfully with tincture of belladonna (B. P.). In one the drug was administered in half-drachm doses every half hour, until the specific effects were manifest, and in the other, "scruple" doses every hour. We have seen full doses of opium produce the same effect.

A Russian Medical Congress will be held at Moscow after the opening of the exhibition at that city.

Excision of the Kidney.—Mr. C. Heath, of London, excised the kidney, July 12th. The patient was a young child, and the disease sarcoma. Death occurred eighteen hours after the operation.

Œsophagostamy is a new term to designate the formation of a œsophageal fistula in cases of stricture of the œsophagus. The operation proposed by Mr. Reeves has recently been performed by him upon a male patient, aged sixty, with malignant disease of the œsophagus. At last accounts the patient was doing well.

Dr. Andrew Buchanan, Professor of Physiology, University of Glasgow, died July 9th, at the ripe age of eighty-four years.

Gastrostomy was recently performed by Mr. Langton, St. Bartholomew's Hospital. Patient, a young child; disease, stricture of œsophagus from swallowing lye-water. Result, death one week after operation.

Death Under Ether.—Mr. Lawson Tait, of Birmingham (*British Medical Journal*, July 15th), reports a death from ether. The patient was an anæmic woman, aged forty-five, who had an abdominal tumor. Death occurred during the administration of the anæsthetic, and is believed to have been occasioned by the use of an inhaler by which the patient breathed over and over again the same volume of ether and air.

British Medical Association.—The fifteenth annual meeting of the British Medical Association will be held at Worcester, England, August 8th, 9th, 10th, and 11th. A semi-centennial jubilee is to be held.

Chronic Cases in Bellevue Hospital.—The surgeons of Bellevue Hospital are complaining through the columns of the secular press that the other hospital surgeons of the city send all their chronic and incurable cases to them, thus increasing the mortality of said institution, and crowding the wards with uninteresting cases. The other hospitals repudiate the charge and say that Bellevue is an almshouse hospital, and must necessarily take everything sent to it.

Dr. Samuel Kohn.—By an oversight the title of M.D. was omitted from the name of the author of the interesting article on page 91.

The Late Dr. John W. Corson.—At a special meeting of the Essex District Medical Society, held in Orange, on Tuesday, June 6th, the following resolutions were adopted:

Resolved, That in the death of Dr. John W. Corson, of Orange, this society notes the loss of an esteemed and respected member. He was learned in the science of his profession, and with unusual zeal devoted to it the best powers of his life. As a professional associate, courteous, considerate and without guile himself, it was to his sensitive nature a source of grief and unhappiness to discover the opposite in others. He leaves behind him the memories of a long Christian life, beautified by a steadfast aim to keep, in all things, a conscience void of offence toward God and man.

Resolved, That we tender to his afflicted widow the sympathy of his medical associates in her bereavement.

Resolved, That these resolutions be published in the daily papers.

Wm. J. Chandler, Secretary *pro tem.*

Death of Dr. M. A. Wilson.—Dr. Milo A. Wilson, formerly of this city, died in Denver, Col., of Bright's disease, on the morning of July 6, 1882. He was born in Pittsburg, in 1845, and was the son of the late Dr. R. A. Wilson, and brother of the late Oregon Wilson, the artist. He was at one time one of the surgeons of the Seventh Regiment, and a member of the medical staff of Bellevue Hospital. While in the latter position he became particularly interested in the improvement of the condition of the insane, and made a number of interesting experiments to ascertain the effect of music upon the patients at Blackwell's and Randall's Islands. Dr. Wilson was the author of several medical books.

Original Communications.

TEN YEARS' EXPERIENCE IN THE TREATMENT OF STRICTURE OF THE URETHRA BY ELECTROLYSIS.

By ROBERT NEWMAN, M.D.,

PERMANENT MEMBER OF NEW YORK STATE MEDICAL SOCIETY, SURGEON NORTHWESTERN DISPENSARY, ETC.

PART I.

My paper on the successful treatment of stricture of the urethra by electrolysis in 1874,[1] was an innovation. But contemporaries and followers have confirmed my statements. The success of the treatment has been so unique, that for the last ten years I have treated all strictures under my care by electrolysis. I have waited on purpose for eight years, in order to give a report which allows no doubt. Most of the cases reported in the former paper were treated in 1872, and have remained under observation up to the present time. The object of this article is: (1) To continue the history of the old cases, a record for ten years, which will show that scarcely a relapse has taken place, and all patients so followed up remain well to-day; (2) to relate a few new cases, and give a general outline of cases during these ten years; (3) history of the operation, with methods and cases reported by other practitioners; (4) answers to objections and queries, with new facts and improvements.

I.—I will give the sequels of all the cases reported in my paper of 1874, and continue their history up to date, which is a period of ten years—1872 to 1882.

For history, treatment, etc., of these cases, from 1871 to 1874, I refer to the first paper, not wishing to relate them a second time.

CASE 2,131.—*Traumatic impassable stricture of nine years' standing, treated successfully by the third method of electrolysis.*—Came under observation in 1872. In due time reports well, and passes a sound No. 12 large American scale.

Sequel.—The patient has remained well six years, up to 1878. Then he changed his business and mode of living. Having gone West, he travelled constantly in the country, riding either on horseback or in a buggy, over bad country roads in severe weather, and thereby contracted a new stricture.

STRICTURE URETHRÆ, PERINEAL ABSCESS—PARALYSIS OF BLADDER.

He wrote me a long letter from Ohio, that he acquired this new stricture in the way just mentioned, and for this reason we must call it a new traumatic stricture—certainly not a relapse. The calibre has gradually become so small that his physicians could not pass any instrument, not even a filiform bougie. A perineal abscess complicates matters, as also paralysis of bladder. He has no control over his bladder, neither can he pass water, nor retain it.; the urine dribbles away drop by drop, through an opening in the perineal abscess; wets his clothes and limbs. He wears a rubber urinal, which has to be emptied at intervals by day and night. Sleep is disturbed. Urine is loaded with triple-phosphates, mucus, pus, blood-corpuscles, and albumen. His general health is undermined, he is nervous, careworn, and emaciated.

July 6th.—Having come to New York he called at my office, accompanied by his family physician, an excellent practitioner of first-class standing. On examination the urethra was found inflamed and extremely sensitive. The meatus admits a good-sized sound, six inches and a half down the urethra. From that point the stricture begins, and no instrument will pass it, no matter how small. Ordered rectal suppositories of opium, camphor, and belladonna, and external hot applications.

July 8th.—After patient manipulations a filiform bougie passed the stricture and entered the bladder. Next an electrode bougie, No. 11, French, was introduced and firmly arrested by the stricture; the free end was connected with the negative pole of the galvanic battery. The positive sponge electrode applied over abdomen closed the circuit. The electrolysis was kept up with six cells steadily for seven minutes, when the bougie entered the stricture, pushed slowly forward and entered the bladder. Ordered ten grains sulphate of quinia.

July 9th.—Is so much better that he passes water voluntarily.

July 10th.—Feels good, no trouble, voids urine with full control of bladder, has no straining, passes water easier with a tolerable stream.

July 12th.—Steady improvement.

July 13th.—Quality of urine is improved, less sediment and pus, second electrolysis as before with a bougie, No. 14, French, which passed easily into the bladder. Present Drs. Green and Hund.

July 14th.—Feels better. No untoward symptom, not a drop of blood passed from stricture during or after the operation, has no pain and passes a very fair stream without any difficulty.

July 17th.—Third *séance* of electrolysis, in which bougie No. 20, French, entered easy in five minutes with seven cells current. After this the patient felt so well that he concluded to return home.

It will be seen that in this unpromising and severe case, first, electrolysis entered the stricture, while the pressure of simple dilatation would not do it; second, that only weak currents were used, which I always prefer and recommend, and third, that the intervals between the *séances* were only four and five days. While longer intervals between each *séance* of electrolysis are preferable, this and many other cases show that it is possible to hurry the treatment if circumstances necessitate such a procedure.

Mr. S—— left for home, and for a long time I have not heard from him. As the case was not cured when he left, and the stricture only widened to No. 20, French, reasonably the best result could not be expected. Nevertheless the following letter just received from his family physician tells the sequel until the present time:

TROY, O., May 18, 1882.

ROBERT NEWMAN, M.D., N. Y.:

It was with great pleasure . . . and I hasten to assure you that your patient, Mr. S——, has been in the enjoyment of very good health since our visit to you, and your successful passage of the strictures . . . The stricture has not since closed, and he has been enabled to follow his avocation as clerk. Very truly yours,

J. H. GREEN, M.D.

CASE 2,045.—*Two strictures—Complication of syphilis.*—Came under treatment in March, 1871. Stric-

[1] Transactions of the Medical Society of the State of New York, 1874. Archives of Electrology and Neurology, vol. I., No. 1, page 18.

tures were cured in a few *séances* of electrolysis. This was my first case treated successfully by this method, after I myself had failed with dilatations.

CASE 2,032.—*Two strictures—Chancroid—Failure of dilatation—Success with electrolysis.* — Patient was treated and cured by electrolysis in March, 1872. *Sequel*—Have heard from him off and on; now keeps a hotel in the country; has not had a relapse. A friend of his told me that he remains well (May, 1882).

CASE 2,098.—*Stricture—Spermatorrhœa—Impotence—Melancholia.*—Was under treatment March, 1872. *Sequel*—Has been kept under observation for ten years, without any further treatment after first report, and remains well. After being cured of his ailments he married, and during these ten years became father of eight children, six of them still alive and healthy. Has not received any after-treatment, nor used bougies. Two years ago I passed once a sound, No. 22, French, easily, only to see that the former stricture had not contracted. I meet the gentleman once in a while, and have seen him quite recently, when he appeared to be in perfect health. He resides in Philadelphia.

CASE 2,129. — *Gonorrhœa and stricture.* — Was treated in July, 1872, and stricture cured in three *séances*. Complications were troublesome. *Sequel*—Ten years' observation without any relapse. The gentleman is still in New York, partner in a large dry goods house.

CASE 2,155.—*Stricture and gleet.*—November, 1872. A stricture one inch from meatus was cured in two sittings. *Sequel*—Not heard from; but as it was not an aggravated case, there is less interest in it.

CASE 2,162.—*Gonorrhœal stricture.*—Was dismissed as cured January, 1873. *Sequel*—Was kept under observation for some years. Is now in business in Chicago, but comes to New York often. Have seen him only a few months ago, and expect him here again in July, 1882. Is in perfect health, without having had any relapse or treatment.

CASE 2,164. — *Simple stricture.*—Was treated in 1872. *Sequel*—Patient lives in an inland village in Connecticut. Heard last from him, in 1878, that he has remained well, without any relapse.

CASE 2,165.—*Three strictures.*—Success in one application, 1872. *Sequel*—Not heard from.

CASE 2,179.—*Stricture of three years' standing.*—A tedious case in 1873. When patient went home sound No. 23, French, passed easily. *Sequel*—The gentleman is a business man, and corresponds with me from Louisville. Wrote me last in January, 1832, that he is well, without having had a relapse.

CASE 2,192. — *Three strictures.*—Was treated in April, 1873, with success in two sittings, only two days' interval. *Sequel*—The patient was from Oneida County, and I heard that he remained well for some years. The information came through Dr. Good, after whose death I have not heard from the patient.

CASE 2,204.—*Stricture and gleet.*—June, 1873. In this case the treatment of the stricture cured also the gleet, the latter being dependent on the former. Was kept under observation. *Sequel*—Patient is now established in Utica. Heard from him recently in 1882, that he is well, without having had any relapse.

CASE 2,229.—*Three strictures.*—The patient, a resident of New Haven, was under treatment, September, 1873. The case was tedious and complicated with renal difficulties and paralysis of the bladder. Was cured entirely. *Sequel*—During nine years' observation, the gentleman has enjoyed perfect health, as reported recently by his family physician in New Haven.

This ends our first part. The sequels and observations for ten years of all cases reported in my paper of 1874—thirteen in number—only one case has not been heard from, which being a light one, must be supposed well, as nothing has been known to the contrary.

II.—RECORD OF A FEW NEW CASES, NOT HAVING BEEN REPORTED BEFORE.—Only a few cases will be given here, to avoid repetitions, and only such cases are selected which have been treated so many years ago that the successful result is proven by the lapse of time. Therefore, no recent cases will be recorded. The *modus operandi* and details of the operations will be sufficiently illustrated.

CASE 1,024.—*Three traumatic strictures of thirteen years' standing—Failure of operation and dilatation—Success by electrolysis.*—Mr. L. C——, a resident of Vermont, in 1866 had a fall, and was hurt in the perineum by a rail of a fence, which caused a traumatic stricture. Was operated on by Dr. Bigelow, of Boston. The healing was uneven, and a hard cicatrix remained, which gives rise to a stricture. This cicatrix occasions an irritation and an obstacle to the flow of urine, just as well as to the introduction of a sound. His business necessitates him to travel constantly, which irritates and sometimes causes suddenly a stoppage of urine. On such occasions he needs the help of a medical man at once to relieve him by the introduction of a sound. On one of these occasions a physician made a false passage, which makes the introduction of a sound still more difficult.

In May, 1868, this patient came first under my care. He was in his usual trouble—the stricture had closed, he could not pass water. After eliciting the above history a sound was passed at once, I think, more by accident than skill. But as the turns of his urethra were peculiar, I made the following note for further reference: Pass down into the urethra until the sound comes in contact with the cicatrix, which is five and three-quarter inches from meatus, then withdraw the sound a little, bring it down to a right angle with the body, press downward, a little forward, and then push on into the regular curve into the bladder. He was relieved at once, and the good result was followed up by dilatation with steel sounds. This dilatation gave only a temporary relief. The stricture closed up again in due time.

From 1868 till 1874 this patient came to me in intervals of about one year solely for relief—never for a cure. When he felt the stream getting too small, he got uneasy, and no matter in what part of the country he was, he took the express train for New York, and came straight to my office. There was very little spoken, his errand was known, and I took the instruments in the usual manner, comparing first the explanatory diagram made on his first visit. He generally pulled out his watch, told me he had arrived at seven o'clock from New Hampshire, the next train leaves at ten o'clock, when he must return. This leaves leisure about two hours, which he will give me for the operation. Therefore, he came not to be cured; there was no time for it; he only wanted to be relieved. This was accordingly done, and with fair result.

March 26, 1874.—Mr. C—— arrived again in the evening, more distressed than ever, and therefore with better intentions.

Can hardly micturate, has to strain and only with

difficulty passes a small stream. Meatus will admit a No. 11 sound. Whalebone bougie à boule detects an alteration of the mucous lining of nearly the whole urethra, its touch against its walls conveys a feeling of the finger, like paper and even parchment, the sign of a grave alteration. After two inches down, the whole urethra is a mass of strictures; admitting not more than a No. 6 sound at 5¼ inches from meatus, which spot corresponds exactly to the seat of the old traumatic stricture now nine years old. This third stricture is the worst, as almost all traumatic strictures are. The other two strictures seem to be acquired later, the first is three inches from meatus, which a No. 8 sound scarcely passes. The second stricture is at 4½ inches, admitting tightly a No. 7 sound.

There is an irritation throughout the whole urethra, which is aggravated by the patient's travelling in railroads, the constant jerking causing a nervousness and an inflammation, which has been observed often in patients under similar circumstances. The patient arrived here with the train at seven o'clock P.M., and now thinks he ought to return to-morrow to Vermont; hence the chances for a successful treatment are again doubtful. Nevertheless it was concluded to make the first application of electrolysis.

A weak galvanic battery was used, the wet sponge from its positive pole the patient held firmly in the palm of his hand. The electrode bougie insulated, with a metal end, egg-shaped, No. 11, was introduced into the urethra down to the first stricture, the other end of the sound was connected with the negative pole of the battery, which closed the circuit. The current of the electricity was slowly increased, cell by cell, taking care to keep the electricity as a steady current, without any shocks or interruptions, till fourteen cells were in operation. Progress of the bougie in the urethra was slow, but it moved on steadily until it had passed through all the strictures into the bladder. The third stricture, where the old cicatrix is situated, was the worst, and took about six minutes before No. 11 passed. The electrolitic action was kept up altogether twenty minutes. No pain nor hemorrhage was caused by the operation.

March 27th.—He feels better, passes a large stream; had a good night's rest. Went home to Vermont, but returned again on May 31st. Has felt so well that he comes for a continuation of the treatment; which was done, and the second application of electrolysis made in the same manner as five days ago. Bougie electrode No. 11 passed through two strictures for ten minutes, while sixteen cells were used, then at 5¼ inches the bougie could not be made to sweep around the curve, it being too elastic. Consequently the electrode was changed to a steel sound, and after five minutes went through the worst part into the bladder. The sound was slowly withdrawn, by which five minutes more were used. The whole operation lasted twenty minutes. No hemorrhage nor pain was caused, and immediately afterward he micturated a good stream, admitting that it is better now than for the last eight years.

Patient again absenting himself was not heard of for the next three months. He grew worse and arrived in his usual way on August 31st. The urethra was very much thickened and irritated, and almost in the same state as in March last. The meatus will admit a sound No. 12 old American scale, but is arrested at two inches further on. The seat of the traumatic stricture, explored by a bougie à boule, is so congested and irritated that no instrument would pass by ordinary means. It would not do to risk anything by introducing an instrument which will not pass after hard work. As such a course would even jeopardize the patient's life, a safe and certain plan was made as follows: a small filiform whalebone guide was carefully introduced and with great care advanced forward into the urethral passage. It encountered on its way the old strictures at 3 and 4½ inches from meatus, at 5¼ inches passed with difficulty, and last found its way into the bladder. Then a firm metallic sound was introduced over the filiform bougie, the latter remaining in position and acting as a guide. The sound was made for my purpose of steel, and covered by a smooth surface of gutta-percha solution, by a backing process firmly adhering equally to the steel, and acting as an insulator to the effects of electricity. On the convexity of the curve is a groove for the purpose of allowing the sound to run over the guide easier. On the end of the curve is a small egg-shaped bulb, which is the leader for the electrolysis, and is, of course, not insulated. On the handle of this sound is a small steel wire, to connect with it the negative pole of the battery. This new sound, of the size of No. 6, American scale, introduced over the guide, was firmly arrested at 5½ inches from the meatus; here it was engaged in the old traumatic stricture, and no effort or pushing could move it on. Then this sound was attached to the negative pole of the galvanic battery. The positive pole was held by the patient in the palm of his hand, and the process of electrolysis commenced. The current was increased by degrees from one to eight cells, which made the sound move very slowly through the stricture, and in ten minutes the sound entered the bladder. The electrolytic action was continued, while the sound was slowly withdrawn, altogether lasting twenty minutes. In this case, as in many others, the power and value of the electrolysis is proven beyond any doubt, as no sound would pass the stricture by dilatation, whereas the electrolysis effected the passage by its chemical power of absorption.

September 1st.—Patient rejoices about his improvement, feels easier, has no pain, and passes a tolerably large stream, such as he has not seen for years, and without even a feeling of soreness. He acknowledges his follies, and promises now to come for treatment, as advised. He will not stay here, but will come for treatment as directed. All former efforts were only directed to alleviate symptoms, and the real treatment for a cure commenced with yesterday's electrolysis. According to appointment, patient came to town on September 7th. The large stream of urine has increased since last *séance*, and he feels better in every way.

Electrolysis 2, in the same manner as the last time by metal bougie No. 14, French scale, run over a filiform guide. Eight cells of the galvanic battery were used for seven minutes, when the bougie entered the bladder. The sound was rather tight at the point of the strictures, and without the power of electricity would not move at all, whereas, as soon as the galvanism was added, the instrument soon moved slowly but steadily. This experiment has been tried now often enough to prove that electricity does the work, not simple dilatation.

September 14th.—Electrolysis 3, bougie No. 17, French, passed all strictures in twelve minutes.

September 27th.—Electrolysis 4, with bougie

No. 20 French, passed very slowly and tight with current of fourteen cells, and even on withdrawal made slow progress. This was partially due to an inflamed prostate, which gland was enlarged and thereby encroached on the urethral calibre.

September 28th.—Feels better, had no unpleasant symptom; stream is large, full and forcible, better than for many years.

October 19th.—Prostate gland is normal; general condition is good; fifth electrolysis with bougie No. 22, French scale, passed easier than any time before, without any trouble or pain, ten cells for twelve minutes.

On a subsequent visit patient felt so well that he was considered cured, and ought to be satisfied with a urethra admitting a sound No. 22, French, with a stream of urine correspondingly. Without receiving any further treatment, I heard from him occasionally, and a year ago introduced a sound, No. 23, French, easily. About every six months he tries a sound, just to see if the urethra has not contracted. He continues to travel about, and enjoys perfect health. Last I heard from him was April 10, 1882, when he wrote me a letter from the Crawford House in Boston.

I have related this case *in extenso*, as it illustrates many points in the treatment of electrolysis, and is very interesting and instructive.

Case 2,335.—*Four strictures — Impotence.* — July, 1875.—C. S——, of St. Louis, is troubled with strictures, a consequence of gonorrhœa. Has had other venereal diseases, and suffers now from impotence. Erection takes place only through forced irritation, and even then is incomplete, the penis bending laterally. The sensation in penis is impaired on the right lateral half, whereas it is perfect on the left side. He acknowledges having indulged in all kind of excesses. He also complains of an atony of penis, the member getting smaller in size. He has been treated for the stricture by dilatation by eminent practitioners, without being benefited.

Examination.—Bougie à boule meets distinct alterations of the mucous lining of the parchment feel variety, which travels long distances, from one-half to six inches in the urethra. A large endoscope tube, No. 12, enters meatus easily, but engages in the first stricture and will not pass on any further. There are four distinct strictures, as follows: First stricture is half an inch from meatus; second stricture travels from two to three inches from meatus; third stricture is at five inches from meatus; fourth stricture is at six inches from meatus.

Electrolysis was applied at once. Patient standing in the erect position, had the positive sponge in hand. As negative pole the bougie No. 10, American scale, was introduced into the urethra, nine cells were used for six minutes, in which time all strictures were passed.

For his other troubles external galvanic applications were used.

August 15th. — Electrolysis 2, electrode bougie No. 11. Current of ten cells was used for thirteen minutes throughout the whole urethra. Bougie advanced slow and easy, absorbing the indurated portions of the urethra. No pain, no inconvenience. The third stricture at five inches needed application longest. Ducts were galvanized with strong currents of sixteen cells for one minute.

August 12th.—Electrolysis 3. Positive sponge in hand, negative bougie No. 12 in urethra, nine cells for seven minutes passed all strictures and entered the bladder. Current felt easy and gave no pain.

August 31st.—Electrolysis 4. Bougie No. 14 went through all the strictures into the bladder.

September 16th.—For examination a steel sound, No. 14, was introduced, it passed, but was tight at five inches. No transmission to the fingers was felt at the seat of the other strictures, which shows a decided improvement, and the absorption of the hardened tissues in former strictures.

September 23d.—Electrolysis 5. Last application with electrode bougie No. 16 passed easily and entered bladder without any impediment. Meanwhile his other ailments were treated by electricity in various forms with the best results, so that the paresis and impotence were cured only too well, as he commenced already his old bad habits of excess.

September 25th.—Discharged cured.

Sequel.—Heard from him through friends. He is well and has taxed his regained power only too much. He is a public man, well known, and has too many temptations to indulge in excesses. Has, nevertheless, remained well up to 1882, during seven years, without a relapse.

Case 2,231.— *Gonorrhœal stricture.* — September 29, 1873, Mr. I. L. M—— was accompanied by his family physician from Brooklyn, who was then a patient of mine. He had a gleety discharge, could micturate only with straining, and passed a small stream.

Examination with bougie à boule met a stricture at seven inches from meatus in the membranous portion of the urethra, beginning abruptly and running tight to seven and three-quarter inches.

Electrolysis was done at once with a Stoehrer battery. Positive sponge electrode was held against the thigh. Negative electrode bougie No. 10 was introduced in the urethra down to the stricture; eight cells were used first, and soon after six cells only. The stricture was dilated and passed by the electrolytic action in a few minutes.

October 15th.—The second electrolysis was done with a bougie No. 13, successfully in five minutes, when eight cells were used. I heard that he was well.

November 16, 1880.—I had the opportunity to examine this patient. Found him well, with no relapse, and introduced steel sound No. 13, American scale, in a healthy urethra. Hence no relapse in seven years.

Case 2,256.—*Single gonorrhœal stricture.*—April 22, 1874, R. W——, aged thirty; single; plasterer. Had a gonorrhœa seven weeks ago, took capsules and enough calomel to salivate. Never used injections. Has now a small stream with burning pain. Meatus is large enough to admit a No. 12 sound, but met a firm organic stricture at three and three-quarter inches from meatus. Sound Nos. 10, 8, 6, and 4 were tried in turn, but neither would pass the stricture, which is fibrous and resisting.

Patient was treated in the same way as the previous cases reported, had five *séances* of electrolysis in intervals of about three weeks, the last of which was done July 26th, when a bougie No. 14, American scale, passed the whole urethra easily. He was then well.

Met him in February, 1880. He had enjoyed good health, with no relapse.

Case 2,234.—*Single stricture—Impotence.*—October 5, 1873, D. S——, aged twenty-four years; merchant; was most of his time travelling for his business. He had only one urethritis, which had been checked by a strong injection. He complained of difficult micturition with pain, the water sometimes

mixed with blood. Besides, he felt a general decline in sexual power, and was afraid of getting entirely impotent. On examination with bougie à boule a stricture was found at five and one-half inches from meatus, which was sensitive, painful, and bled on touch. Sedative injections were ordered and some external electrical applications.

October 22d.—Electrolysis with bougie No. 10 as negative passed the stricture with a twelve cells current in eight minutes.

November 6th.—Repetition of electrolysis bougie No. 11, current seventeen cells.

December 12th.—Electrolysis bougie No. 13, American scale, entered easily in a few minutes. The patient is small in stature, and therefore a calibre of No. 13 is a larger urethra than normally can be expected. Therefore he was discharged as cured.

Sequel.—The gentleman travelled to Europe, South America, etc., and for this reason was absent several years from New York. On his return he called. He was in good health, never had any trouble with his urethra; but was somewhat afraid of impotence. I saw him off and on. About six months ago he asked my advice in regard to marriage. The advice, to marry by all means, was followed with fear not to be able to execute his marital relations. Now the gentleman comes for an anti-aphrodisiac, as he got into the other extreme.

Nevertheless he is perfectly well, and had no relapse. I see him often, and he was at my office only a few days ago, June, 1882. Therefore this case has been under observation nine years.

Case 2,339.—*Two strictures.*—September 10, 1875, Mr. B. A——, aged twenty-nine; from Chicago, suffers for the last five years from stricture, which originated through strong injections of chloride of zinc and carbolic acid. He has been under treatment by gradual dilatation, which was carried out to sound No. 9, but was not successful. As soon as the dilatation was discontinued, a relapse followed, and the calibre of the urethra contracted again. The stream is now very small, admitting only a No. 2 bougie.

Whalebone bougie à boule No. 2 passes with ease down to five inches from meatus, where it entangles itself in a fibrous stricture, and with difficulty can be pushed into it for one-quarter of an inch.

Electrolysis. Bougie electrode No. 9, as negative, is introduced into the urethra, positive sponge in hand, current of nine cells for eight minutes. No pain. The bougie advances very slowly, and finally passes through the stricture, which is nearly one inch long. At six inches the electrode is entangled in a second stricture, in which it advances into the curve to nearly seven inches. The whole urethra from five inches downward is a mass of fibrous, cicatricial tissue. A little hemorrhage followed this application.

October 2d.—Electrolysis 2. Negative electrode bougie No. 11 advanced slowly for fifteen minutes, while eight cells were in operation. The tissues are much altered.

October 14th.—Patient has felt much improved, stream is full now, and without any impediment.

Electrolysis 3. With bougie No. 13 for nine minutes, six to eleven cells were used, gradually augmenting and regulating the current of the battery.

October 28th.—Electrolysis 4. Bougie No. 14 with six cells for eleven minutes. Did better than on any of the former applications.

November 26th.—Patient feels well, and wishes to return home. The introduction of a steel sound No. 14 showed that the urethra was restored to its normal calibre, without finding any of the former hardness.

Sequel.—January 11, 1881. The patient called, stated that he had enjoyed good health, without having had any relapse of the stricture. I then introduced a sound No. 14, which passed easily into the bladder.

This case is important, as it shows that electrolysis cured the strictures, without getting a relapse in five and a half years; whereas before the patient suffered for five years, in which time dilatation only relieved temporarily, the strictured parts always recontracting. Hence it proves that electrolysis has not solely a power of dilating, like an instrument, but the chemical action of absorption, which is claimed for it.

Case 2,345.—*Stricture—Gleet—Cystitis.*—January 10, 1877, C. R——, aged twenty-four; was sent by Dr. Brink, of Saugerties. Is distressed with painful micturition, passing a small stream, has gleet and cystitis. Had one stricture at five inches, very hard, so that it could be felt by external digital examination. Patient was treated with suppositories, warm applications, emulsions, etc.

January 20th.—Electrolysis with bougie No. 12, large scale. Battery was weak, just suiting this case, sixteen cells were employed for fifteen minutes most of the time, the electrode being in contact with the stricture, which could be felt as a firm ring, and gradually absorbing, getting softer and yielding. Patient went home, and on his next visit had another *séance*, in which bougie No. 13 passed easily. The whole urethra appeared restored, and patient left for the country.

Sequel.—June 24, 1878. Patient made a visit, reporting that for eighteen months he has been well, without having used an instrument in his urethra. He was then re-examined with a sound No. 13, which passed easily, without finding any trace of the stricture or any contraction. It was also considered that a calibre corresponding to a No. 13 sound, is a large normal urethra, and that our patient never had, nor needed a larger urethra.

Our patient has made a visit once every year, to ascertain if he is all right. On all these occasions I have re-examined with a sound No. 13, once even with a No. 14, and found his urethra healthy.

Case 2,382.—*Three strictures, gonorrhœal.*—May 20, 1877, J. T. R——, aged twenty-four; Baltimore. During eight years has had gonorrhœa five times. Has had orchitis badly several times. Has been treated with bougies, once a No. 16, French, was used, without much benefit. Stream of water is flattened on itself, and then crossing and splitting in two opposite directions. Formerly indulged in venereal excesses.

Examination.—Penis rather short sized, meatus large. Whalebone bougie à boule finds three strictures. First at three and a half inches from meatus, feels on touch like paper. Second stricture is at four and a quarter inches. The principal and third stricture is found at five inches, transmitting to the fingers a feeling like parchment, also an indurated mass spreads from anterior wall of urethra in deeper tissues, encroaching thereby the calibre of the urethra.

Steel sound No. 19, French, feels the first two strictures distinctly, but is arrested by the third at five inches. Steel sound No. 16, French, enters bladder by slow and careful management.

May 26th.—Electrolysis. Bougie No. 11, American scale, with an electric power of six cells for eight minutes, passed all strictures and easily went into the bladder.

May 27th.—Is doing well, with no unpleasant symptoms. Went home to Baltimore and returned as agreed on.

June 16th.—Electrolysis 2. Bougie No. 12 easy, only six cells were used, but for fifteen minutes steadily, and with good effect. Ordered ten grains quiniæ. Felt well, and left for home next morning.

July 8th.—Electrolysis 3. Bougie No. 13 went slowly in bladder; ten cells were used.

August 13th.—Electrolysis 4. Bougie No. 14 passed slowly, with ten cells for twelve minutes. Patient went home, considering himself cured, and feeling excellently.

Sequel.—Has come several times to New York for a re-examination. Every time found him well, and a steel sound No. 14 passed easily into the bladder, without encountering any obstacle.

March 7, 1882.—A letter was received, saying patient feels well, without having had any unpleasant symptoms since.

CASE 2,389.—*Three strictures of sixteen years' standing—Failure by dilatation—Cure by electrolysis.*—June 23, 1877, J. M. E——, aged thirty-two; Boston; has suffered sixteen years from stricture, for which he has been under treatment, without getting much benefit. Most of his physicians have used dilatation, which gave temporary relief, but soon after recontraction took place, making his case worse. Has a burning pain in the urethra and gleety discharge.

Examination.—Meatus is small, but on a stretch admits a No. 11 sound. First stricture is 2½ inches from meatus, which a sound No. 9 will pass; the second stricture is at 4½ inches, allowing a sound No. 7 to enter; the third stricture is at six inches, very small, through which no sound will pass, only a small whalebone guide No. 1, nearly equal to a No. 6 French scale. Micturition always takes him some time and efforts before the water begins to flow; the stream is small and corkscrew like.

Electrolysis. Bougie No. 7 passed two strictures and engaged in the third, where the electric current was continued for some time. The stricture began to absorb, widened, but not enough to let the bougie pass. Further operation was then suspended, having advanced sufficient for the first *séance;* besides the patient had to return to Boston to-day, and therefore could not be overtaxed.

July 7.—Patient came with the night boat from Boston, and reports that he feels improved since last operation. The anxiety is relieved, his stream is natural and larger, without pain.

Electrolysis 2. Bougie No. 15 French passed all strictures and into the bladder. At 6½ inches a soreness is encountered, which bleeds easily.

July 28th.—Electrolysis 3. Bougie No. 19, equal to Tiemann's No. 10; ten cells for five minutes had the desired effect. Tincture gelsemin was ordered, more to relieve the straining in bladder.

August 11th.—He feels better; is improved in every way; gelsemin has done well.

Electrolysis 4. Bougie No. 21, French, equal to No. 11, American, with eight cells electric current for nine minutes, passed with greater ease than any time before.

August 25th.—Examination with the endoscope shows some granulations, which bleed on handling, and were touched with tincture of iron. Then electrolysis 5 was applied, with a bougie No. 24, equal to No. 13, American, which passed nicely through all the strictures into the bladder.

September 11th.—Electrolysis 6. Bougie No. 14, American scale, was worked up well with weak currents.

September 22d and 29th.—Large endoscopic tube passed easily and showed a healthy urethra.

Patient was discharged cured.

Sequel—This patient has enjoyed good health since. In the following year I saw him several times, and for a slight discharge touched a spot in the urethra through the endoscope. Then for a few years I saw him annually, on which occasions an examination was made with a sound, which proved that his strictures remained cured, without any relapse having taken place.

CASE 2,392.—*Stricture, gonorrhœal—Failure with dilatation—Cured by electrolysis.*—August 12, 1877, A. T——, aged forty years; Boston. Is suffering from a stricture for the last fifteen years. Had his first gonorrhœa twenty-five years ago, and for a whole year gleet. The next gonorrhœa he had fifteen years ago, which discharged for two months. Soon after felt that the stream of water became smaller; sounds were passed. He indulged also in venereal excesses; got weak, and his whole constitution run down. He was nervous, and the stream of water became still smaller. Eight years ago a systematic treatment was commenced for the stricture by gradual dilatation, and carried on to large-sized bougies. Afterward an irregular physician gave him medicine and external applications of electricity, after which he had retention of urine. Then he again had a regular physician, who used bougies for dilatation. Next he found an eclectic practitioner in Boston, who used induced currents of electricity, gave him medicine and suppositories with apparent success. The prostate was also cauterized. Then the patient used a mineral water of magnesia and sulphur in Brunswick, Vermont.

August 12th.—At present the stream is small, but generally straight; meatus is a little irritated and red; urethra at times feels all right, at others there is a grating sensation a few minutes after micturition; sometimes has a pain over fundus of bladder, and an internal irritation at the neck of the bladder, running toward the rectum. Is generally costive, very nervous, and anæmic. Urine dark yellow, a little cloudy; specific gravity 1,025; slightly acid, a little mucous, otherwise normal.

Whalebone bougie à boule enters the urethra easily. At four inches from meatus a thickening begins in the walls of the urethra; it feels like paper; more so in the anterior wall. The first stricture begins at five inches, where the mucous lining is more indurated; a sound No. 9 passes in, and is arrested at 5¼ inches, where the stricture is still smaller and more fibrous. A sound No. 8 passes the end of the stricture and then slips into a wider canal. At seven inches another stricture and induration is encountered; then bougie passes on easily, and at 8½ inches enters the bladder. The prostate is not enlarged; the endoscope shows no granulations; urethra looks rather anæmic.

The treatment for these strictures was electrolysis by weak currents and prolonged sittings. Four *séances* were held from August 12 until September 24, 1877. Electrode bougies gradually increased from No. 9 to No. 12, large American scale. One application lasted twenty-three minutes, but the current was weak, so that not the slightest pain or even inconvenience was caused. The absorption of the strictures was perfect, and patient left well.

(To be continued.)

A PLEA FOR A MORE THOROUGH STUDY OF CHEMISTRY IN MEDICINE AND THE ARTS.

By J. H. BILL, M.D.,
SURGEON, U. S. ARMY.

An architect about to build a substantial house plans a solid foundation for the structure; only shanties rest on the ground of totter on poles. Usually the foundation is invisible, but we feel sure of its presence notwithstanding. Every fine house has a foundation.

The figure, when applied to education—in the present instance to medical education—although well worn, is too apposite to require apology. Much of the present medical education is mere shanty-building.

To be definite, I would call attention to the neglect of chemistry and physics as a foundation for a sound medical education. The fact is notorious, although the evidence thereof is somewhat indefinite. I offer these remarks without hesitation, for I think I can supply this evidence.

For several years past the writer has been a member of a board for the examination of candidates for the position of assistant surgeon in the Army. This board has searchingly examined over five hundred men, graduates in medicine, many graduates in arts also, but of this whole number not more than two or three had any knowledge of the elements of chemistry, and most were ignorant of the fundamental principles of physics. So flimsy is the chemical smatter possessed by most of the candidates that it has been found difficult to propose questions within their comprehension. The few men who satisfied the board that they understood the principles of chemistry, got their chemical education before studying medicine. I am satisfied that the so-called courses in chemistry of our medical colleges fail entirely in their object. To show how hard pressed the board has been and is now, to find questions sufficiently simple, I give some of the questions actually propounded. These questions will fairly represent, in point of difficulty, the ordinary average examination:

Name a poisonous alkaline earth.

Mention by name four monatomic alcohols.

Give the qualitative composition of urea—of uric acid.

Formulate the process commonly used for making hydrogen gas.

What is common aldehyde?

How is phosphorus obtained?

What is plumbago? What is silica? Does it occur in the vegetable kingdom?

Is casein a nitrogenous body? Is gelatine?

Cause and removal of hardness of water.

Antidote for poisoning by salts of barium.

Difference between quantivalence and equivalence.

Fundamental law of the refraction of light.

What is chromatic aberration, and how prevented?

What is the "return-stroke" of meteorology?

How is the rainbow produced? Explain the secondary bow.

Explain the phenomenon of fluorescence.

What is specific gravity, and how got?

Cause of pitch of musical sounds.

Name four sources of electricity. How is the electricity used in lighting got?

How does a double-convex lens magnify?

The board has been limited to questions of this easiness because candidates could not answer more difficult questions, and most failed to answer even these. It should be considered that most candidates prepare specially for this examination, taking from one to six months, and that the whole tenor and scope of the examination favors the man who really has something to exhibit.

It is a matter of the utmost importance that both instructors and pupils should recognize the importance of a thorough grounding in the physical sciences before the study of medicine proper is begun. It is very certain that the higher rewards in medicine will be for those who have been educated in this manner, especially in chemistry, and if we expect in the future to lead in medical research, as heretofore we have been contented to follow, our students must begin the study of medicine with a more intimate acquaintance with the sciences from which medicine draws assistance. Among these sciences chemistry is the most important for a beginner to have mastered.

In the first place the study of chemistry adds to the stock of useful knowledge, particularly useful to the medical man—often indispensable to him. There is little to be said about the advantage of this kind of knowledge, for all will admit, the more of it the better. The trouble, however, lies with the memory. We are most of us not Macaulays. We forget far more than we know. But the man of weak memory need not despair on this account, for, if knowledge is once properly got, although in the stress of more practical studies, or living pursuits, it may be crowded out and hide itself, the mind nevertheless will be able without hesitation to refer to the treatise where the fact or theory mislaid, but not lost, is preserved. A scientific man is no more expected to carry his knowledge around with him in his head, than is a surgeon expected to carry his armamentarium in his coat pocket. It is knowledge still, only not ready knowledge. The facts of chemistry and physics, on which physiology now rests, we must of course keep before us and carry with us. Such are the established laws of hydraulics—light, sound, and electricity (as refraction, induction, vibration, etc.), and in chemistry the composition of the blood and of the aliments—the changes effected by respiration, digestion, exercise, etc., the chemistry of urea, uric acid, glycogen, etc. These are a very few among a great many chemical facts that a physiologist must know and keep in sight. Most students find these facts difficult to master in the school of physiology.

In the second place chemistry properly studied will cultivate the intellectual powers in the best manner, and form mental habits of the greatest value to the scientific medical man. Its capabilities of developing both analytical and synthetical power are almost as great as the mathematics, and with this superiority over the mathematics, that its training is more practical, its analysis and synthesis is more like that of medicine and the habit of thought, and action which it engenders resembles that which every scientific medical man should strive to hold.

Let us briefly review the process by which a chemist analyzes a substance.

Take the simplest case. We first effect the solution of the substance, we then acidify with chlorhydric acid, by this silver will be precipitated. Left in solution we have copper, mercury, lead, bismuth, etc., iron, chromium, zinc, etc., the alkaline earths

and the alkalies. We add to the solution sulphydric acid gas. The copper, mercury, lead, and arsenic, antimony, and tin groups of metals are precipitated, the first dark, the latter light colored. The solution contains the iron, zinc group, the alkaline earths, and the alkalies. Ammonium sulphydrate precipitates the iron group, the solution contains the earths and the alkalies. Ammoniums, carbonate and chloride, precipitate lime, baryta, strontia, leaving magnesia and the alkalies in solution. Sodic phosphate precipitates this magnesia, the solution contains soda, potash, and lithia. We add chlorhydric acid, evaporate to dryness, and exhaust the chlorides with ether so we get lithia in solution and potash and soda in the form of chlorides, whose aqueous solution can be tested. But no residue in our supposed case is left. We therefore test the ethereal solution by the flame, and if this is satisfactory our experiments have told us two things, first, that lithia is present, and second, that all things else are absent.

We can apply this method to medical research, as for instance, a patient complains of "shortness of breath." The temperature and pulse are about normal, this excludes all active inflammations, including acute pleurisy, pneumonia, etc. There may be present chlorosis and leucocythæmia, emphysema, hydrothorax and pulmonary apoplexy, heart disease, aneurism, intercostal neuralgia or rheumatism, and Bright's disease. Auscultation and percussion, etc., show that the air is properly penetrating all portions of the lungs; apoplexy, hydrothorax, emphysema are, therefore, absent. The microscope shows the blood-cells normal; chlorosis and leucocythæmia absent. The chest expands without let or pain; no neuralgia or rheumatism. There is no palpable tumor nor abnormal sound heard over the great arteries; aneurism excluded. There is something wrong about the heart, this means valvular disease or Bright's disease. The rhythm of the heart-sounds is perfect; no valvular disease. There is hypertrophy of the left ventricle; Bright's disease present. We confirm by the test-tube and microscope. A case, of course, can hardly occur with the simplicity and freedom from complications set forth. As a diagram it will serve our purpose to illustrate the application of the analytical method to medicine. I think that skill in the analytical method of chemistry will bring skill in the analytical methods of medicine.

But there are certain habits of thought and action produced by analytical chemistry that are of the greatest value to the medical man. If we train a lad (and the training may commence at thirteen years of age) in analytical chemistry, what habits will he get?

Firstly, his judicial power is increased. He learns particularly to suspend judgment. For example, let a dark blue solid be presented for examination. To an untrained mind the temptation to guess its composition is almost irresistible. It is blue, it is solid, the man who presented it is a dyer, it looks like indigo—in short it is indigo; so says the man untrained. The chemist says nothing. Resting in the faith that his science will presently give him the information sought, he is quite agnostic, almost incurious. The substance is what it shall prove to be. This is all to him. He applies his analysis, and is told that the substance is prussian blue. Every man who practises medicine, and every man who makes research in medicine, must have this power of suspending judgment. Most get it only after they have practised for some time and with tribulation of the spirit. He who already before studying medicine has been taught to believe that "we shall see—what we shall see" has a great advantage while his shingle is yet green. This point is obvious and needs no further illustration.

Secondly, and flowing from the first advantage, is humility and docility—teachableness, if I may use the word. A true chemist feels after a while that he knows nothing but what his analysis tells him, his mind is like a blank tablet on which a higher power is to write the truth. This makes him humble, makes him all his life a learner, his mind ever receptive. Such an one is not ashamed of his mistakes, and is able to take advantage of them. A physician so trained will as readily tell of his failures as of his successes.

Thirdly, chemical analysis teaches precision. This is particularly true of quantitative analysis. Milligrammes are usually very insignificant particles of matter, but analysis enforces respect for them. There is not a great difference between orange and yellow, yet one may mean antimony, the other arsenic. In this direction its discipline is as rigid and inexorable as is that of the mathematics. In examining candidates it has seemed to me that the most frequently occurring mental defect is lack of precision of thought and of method, and from this comes all the parrot talk about "impurities of the blood," "concoctions of the humors," or "spinal depravity," or what not, according to the fashion of the time.

Fourthly, allied to precision is cleanliness. Analysis demands absolute purity. Witness the scrupulous care taken in juridical examinations for arsenic, or other poisons. A test-tube may look perfectly clean, but the careful analyst will never assume that it is so; he makes it so. Thus only can he be sure that the results he gets belong logically to the operation he has performed. Trained in chemical analysis the cleanly scientist will not allow a method or an argument to plant itself in his work, to mar, or weaken his statements of facts, or discovery. A finical cleanliness is as important in the physician as in the chemist. It is essential to prescribing Each substance ordered not only should have a precise object, but all other substances, not clearly indicated, should be excluded as matter in the wrong place, or dirt. So, too, incompatibilities will be remembered, and avoided. As an instance of scientific uncleanness I may mention the supposed discovery of a syphilitic germ, a few years ago, when the investigator mistook an unimportant and uncharacteristic body for an organization peculiar to syphilis. The supposed discovery of a measles germ in hay was accounted for in the same way.

Finally, analysis encourages a habit of truth. It will not reform a liar, to be sure, but it will teach a man at least not to deceive himself. It will teach him to discipline his hopes and wishes, and subordinate these to facts. By nature we try (and always succeed) to persuade ourselves that things are as we wish them to be, that facts are as we preconceive them to be. It is wonderful to what extent the ordinarily truthful man will deceive himself. But a man who has formed the habit of reporting his chemical work in simple truthfulness will probably carry the habit into his medical life. A student making his first autopsy should feel no temptation to find wonders. His business is mechanically to report what he sees or what his other physical senses tell him, without adding to or taking away. He must forget how to gloze.

A student, from the pharyngeal spasm and other symptoms of hydrophobia, may theorize that the disorder is the result of disorganization of some centre in the medulla. Presently he has an autopsy of a patient dead of the disease. Unless he knows how to govern his feelings he really sees the centre harder or softer (as the case may be) than normal, because he knows it ought to be so if his theory is true. He has gone out to make facts, not to find them. He has made a confusion which some one must put in order. It is not the intentional liar who harms science (and the best of men morally may be quite incapable of telling the scientific truth), but it is the man who has not learned to distinguish fancies from facts.

But the study of synthetical chemistry as an educator, may also be made of the greatest use to a medical man. Most of the daily routine work of the physician is synthetical. It is important that it should be trained synthesis. A woman consults a physician for a mysterious painful affection of the knee-joint, which has bed-ridden her for years without worsening. A little examination shows the doctor that there are no facts here to discover beyond what the woman tells. He properly forms a theory or guess. He says to himself this woman has hysteria. He then searches for those symptoms that are signs of hysteria, but meanwhile begins a treatment which, if successful, may be the best sign of all. Circumstances frequently force this method upon us. The process is quick, the result brilliant, but for the untrained the method is dangerous. The uneducated man is always forgetting that his guesses are not necessarily facts. The speed is exhilarating, he seems to cut a dash, but it is soon evident that the horse he thought he was driving, is really running away. In the case we have already considered he will rashly tell the man who complains of dyspnœa that he has *the* asthma, deliver him a lecture on the bronchial tubes, and drug him with chloral or cannabis. For the sake of speed or his own ease, or for ostentation, he has failed to use a method which at least would have given him safe results, and he has needlessly used a method that gives safe results only when used with prudence and care, in an imprudent, careless manner. To synthetize properly is to guess first, and then find facts in support of the guess. He guessed the man had asthma, but he did not trouble himself to find facts to prove it.

In scientific medical research this vicious style of guessing is even more prevalent.

The practice of synthetical chemistry, or even the careful study of the synthetical labors of others, will teach a man the scope of synthesis in medicine, for the conditions of its exercise are about the same in medicine as in chemistry. As we have seen the physician making his guesses, so also the chemist guesses. He guesses, for instance, that a substance has a certain composition, and he records that guess in a constitutional formula. He then tries to make the substance by putting the elements together. If his hypothesis is correct (his chemical knowledge being sufficient) he will succeed in doing this, and his success proves his proposition. But how many fine-spun theories—as, for instance, the constitution of uric acid—when the attempt has been made to verify them synthetically, have come to naught. The young synthesist, like a young setter, learns more from the mistakes than from the successes of himself and others; the wariness and ever-present consciousness of fallibility created by these failures and mishaps are qualities of the highest scientific importance. The practice of synthesis in all science after this wariness has become second nature is a matter of scientific imaginative power; in a word, of genius. This imaginative power can be greatly increased by practice, and synthetical chemistry will increase it for use in medicine. Here, then, are two capital advantages resulting from the study of synthesis in chemistry.

Few students can practise synthetical chemistry, for few have the ready knowledge, to say nothing of the time and material; but every student can examine the labors of others, and as synthetical chemistry is as yet meagre (being not yet fifty years old), it will be an easy task for the apt student to master the methods and results already obtained. Among these synthetical studies stand, first, Liebig's and Wohler's experiments on the artificial production of urea, Frankland's method of making the radicals from the corresponding alcohols by acting on an iodide of the radical with zinc, the method of ascending an homologous series from one alcohol to the next above in the series by saponifying the cyanide of the alcohol from which we wish to ascend, and so getting the acid pertaining to the alcohol to which we wish to ascend, and thence the aldehyde, and then the alcohol itself; the making of the higher benzenes according to the process of Fittig and Tolens—as toluol xylol, etc., from benzol—with the light thrown into the benzine group, as well as the creation of many isomeric hydrocarbides previously unknown (a most beautiful example of synthetical practice), the discovery of the polyatomic alcohol series by Würtz, the labors of Hoffman and Perkins in the coal-tar products, and later, the syntheses by Kekulé, Bayer, Grabe, and Lieberman of alizarine and indigo. These are some—perhaps a third—of the synthetical processes of chemistry. After he has mastered the details of these processes, the student can try some synthesis for himself. Let him imagine the constitution of any organic substance, and then let him hunt for facts supporting his hypothesis. It is in this way that the student can learn the scope and true place of the imagination in science, both medical science and science in general.

I have said nothing of the fascination of this study as compared with the dry didactics and legerdemain of the chemical lecture course, nor of the beauty of the several processes, the ingenuity of the methods, the fertility of the invention, the logical sequence of the results, the feelings of surprise or admiration as some long vista of chemical relations is brought into view. The able instructor can understand the advantage he has with his pupils when mental discipline and pleasurable emotions flow from any course of study.

The need of the present is not a post-graduate but an ante-medical course. If a man has but three years to devote to medicine, he had better spend the first year in the exclusive study of chemistry and physics, and chiefly in the laboratory and closet. I do not believe that there can be much progress in scientific medicine in this country until great changes are made in the preliminary training in chemistry and physics.

NEW YORK, August 1, 1882.

AMYL NITRITE.—An Italian physician asserts, from practical tests upon rabbits, that amyl nitrite is not an antidote to chloroform as has been stated.

SOME OBSERVATIONS ON THE PROPHYLAXIS OF HÆMORRHOIDS,

And their Treatment by the Methods of Dilatation and Hot-water Irrigation.

By JUNIUS LEVERT POWELL, M.D.,

Assistant Surgeon U. S. Army.

Apropos of two excellent papers which appeared in the Record of May 13th and 20th, on the treatment of hæmorrhoids by the dilatation of the anal sphincters, I have been induced to formulate some views of mine upon their prophylaxis and treatment, a part of which are founded upon the known effects of a certain surgical procedure, when applied to other pathological conditions, and which I propose as an auxiliary measure to the method by dilatation.

A thorough knowledge of the anatomy of the lower bowel, in connection with the operation for malignant growth of that organ, is an important item, it is true, for upon the nature of the histological elements, not only of the tissues about the anus, but for some distance above it, is the surgeon enabled to judge of the possibility of reconstructing out of new material brought down from above, an organ fully capable of performing an office that nature never intended it should perform. This vicarious function, imposed upon what at first sight would appear to be totally dissimilar structures, is but a single instance of the vast field of resource which scientific research is, from day to day, opening up to be utilized by surgical skill; but so far as this knowledge affects the treatment of hæmorrhoids, it is questionable whether it is a matter of such vast practical value. Whether we have one or more sphincters, or whether we shall designate by the name of sphincter one or more annular aggregations of normal muscular tissue of greater or less volume, at various distances from the external orifice, does not materially affect the result of treatment in case of the malady under consideration. Hæmorrhoids have their seat in the lax submucous tissue of the rectum about the anus; and, when external, in the loose connective-tissue sheath, so to speak, which surrounds the sphincter ani. The causes of this condition cannot be summed up in a single word, but may be said to proceed from several sources. They may be local, or they may be systemic, the local pathological state consisting of a congestion of the venous radicals distributed to the structures above alluded to. This is all clear and simple enough, but when we go to speak of the *fons et origo* of the trouble, we are dealing with a somewhat more difficult problem. The majority of cases of piles that I have met with give the history of a troublesome local itching about the fundament, preceding for a longer or shorter time the venous engagement. This I believe to be eczematous in character, and in many instances, upon close inspection, have I been able to discover here and there, on the inner surface of the sphincter, what appeared to be a matured vesicle. At the same time, the entire muco-cutaneous surface is dry and hot, and deficient in any lubricating secretion to facilitate the passage of fæces. The consequences of this condition are apparent. *Ubi irritatio, ibi afflucus.* We, in turn, have as an effect the venous engorgement, which eventually ceases to be an effect, but itself begins to reinforce the already existing cause. Thus, a coagulum of blood, whether located in a dilated pouch, formed from any portion of a venous radical, or extravasated into the loose connective-tissue adjacent to the part, acts just as would any other foreign body.

I have thus alluded to what I conceive to be the most potential local agencies in bringing about piles, while I dare say there are others of minor value which might be taken into consideration. But this paper is not intended to be a complete essay on the subject of hæmorrhoids. Its purpose is merely to bring to the front, and emphasize them, points in the pathology of this morbid state which do not appear to have been invested with the importance they possess as factors in the development of the disease, and from them to deduce the most rational modes of treatment. Having spoken of the local causes, I shall now speak of the systemic. This involves a consideration of the venous distribution to the rectum and anus. If, as M. Verneuil maintains, the superior hæmorrhoidal veins are only in connection with the portal system, and form internal hæmorrhoids, while external hæmorrhoids are formed from the middle and inferior hæmorrhoidal veins, which are connected with the general venous system, and do not, except perhaps in the most remote degree, form connections with the superior hæmorrhoidal veins, then we have something like a key to open the way to an explanation of the modus operandi of internal medication, and a guide for the indications in treatment.

Internal and external hæmorrhoids thus become amenable to different measures for their relief, or rather those which apply to the one are not so applicable to the other. It is self-evident, that whenever an obstruction is offered to the free flow of the blood through any of its channels, there must be a backward stasis, beginning at the point of obstruction, and this is a condition we frequently meet with in the abdominal circulation. All those causes which produce congestion of the viscera of this region, such as chronic malarial poisoning, protracted exposure to a hot southern sun, or what not, are likely to be followed by such a result, and hence we may naturally expect to note as one of the consequences of an engorged liver, spleen, or intestines of long duration, a similar condition of the venous plexuses distributed to the lower bowel. But, while this is true, I do not mean to assert that there are not other conditions which tend to superinduce this varicose state, such as a faulty nutrition of the coats of the vessels, associated with or consequent upon a defective nerve-supply, by which they lose their tone. However, it is to this engorged state of the venous plexuses, when in an advanced stage, that we apply the name of internal piles, and it is to this condition that I wish to address some remarks, as to mode of treatment. To be brief, I shall illustrate it by citing the following case: J. J. H——, a soldier of Company "C," 1st U. S. Infantry, a man some forty to forty-two years of age, and quite intemperate habits, was admitted to the Post Hospital, at Fort Stockton, Texas, on July 8, 1881, suffering with hæmorrhoids. He had been treated at a distant station, and the papers had been made out for his discharge from the service, on the ground of total disability. When I examined him, I found two or three tumors about the external orifice of the anus. He stated that at stool, the bowel was in the habit of prolapsing outside the sphincter, and that the act of defecation was attended with the discharge of blood. An examination by introduction of the finger into the rectum was unsatisfactory, though I was satisfied there was an unhealthy condition of the mucous membrane of the bowel. Having the

night previous administered a brisk cathartic, and on the following morning directed a good-sized enema, I determined to dilate and make a thorough ocular examination, which I did, the patient being under ether, by introducing my fingers into the mouth of the bowel, as one would into the mouth of a tobacco-bag that had been tightly closed by drawing on the string. I stretched the sphincter as far as the walls of the outlet of the pelvis would permit, and made a satisfactory survey of the interior of the bowel, which I found in a congested and relaxed state for some distance up, with two or three prominent varicose enlargements, sessile in character, and located just above the sphincter. While an assistant aided me in keeping the sphincter on the stretch, I applied nitric acid freely to the enlargements I have spoken of, but left the other portion of the bowel, which presented the appearance of a mass of coagulated blood, and had a gelatinous pulpy feel, in an undisturbed state. The external tumors I ligated and split open. The man suffered with trifling constitutional disturbance, and in a few days I inaugurated a mode of treatment, to which I wish to direct especial attention. This was the daily irrigation of the bowel, with water, as hot as the patient could bear it. The method I adopted to effect this was the introduction of a large-sized silver catheter up into the gut, until the fenestra near its point had just cleared the internal sphincter, along side of which I subsequently carried the nozzle of a Davidson's syringe, with the other end resting in a vessel of hot water. This plan might have been effectually carried out with the patient in the recumbent posture, the buttocks resting on the edge of the bed, but as it was, he was able to stand, so I directed him to lean over a chair, while the pumping process was carried on. At each compression of the bulb, the water returned through the catheter into a vessel placed to receive it, but now and then, in order to be sure the entire hæmorrhoidal surface was reaping the benefit of the hot irrigation, an assistant, who held the catheter in place, was directed to place his finger on the end of it, thus acting as a sort of stop-cock to allow of the accumulation of the water in the bowel, upon the removal of which it again resumed its flow. At the end of some weeks, I had the satisfaction of being able to discharge the man from the hospital entirely cured.

As I have already observed, the effect of water, at a high temperature, when continuously applied to the tissues, is perfectly well known, but I have seen no mention of its use for the purpose or after the manner I have indicated. Dr. Emmet, in his admirable work on gynecology, asserts that hot water vaginal injections, when used for the various forms of disease in the female organs of generation, have not merely a local effect, but are more far-reaching, and directly or indirectly influence the whole pelvic circulation. Of course, the vascular supply to the rectum must be covered by this observation. If, then, hot water will effect, as thus applied, what is claimed for it, we have in it a simpler and a safer method, and one easier of application to the relief of a disease which has heretofore been relegated to the domain of grave surgical procedures. The medicinal or internal treatment next claims attention, and constitutes, in certain conditions, no unimportant auxiliary to the surgery of hæmorrhoids.

From time immemorial an important measure in the treatment of piles has been to keep the bowels open, since one of the most constant conditions to be combated is constipation. Nothing in my experience has given such satisfactory results in bringing about a regular and laxative state of the evacuations and in relieving the chronically engorged state of the abdominal viscera, when it exists, and which I have termed systemic, as the use of the Hunyadi János mineral waters, taken in appropriate doses an hour or so before breakfast. Except in a very few instances, the effect is sure, prompt, and easy, and the patient is not left after its action with his bowels more firmly locked up than before.

For the pruritus in and about the fundament, or whether the itching exists or not, I prescribe, as a local application, a little sulphur, about gr. x. to vaseline ʒ j., and direct the patient, about once a day, especially if there is any disposition to the formation of tumors on the external anus, to bathe the parts well in water as hot as he can bear it, using a soft sponge in the process. I believe the hot water, besides being a nerve-stimulant, is also an active promoter of absorption, and thus assists in hastening the removal or checking the formation of blood-clots. Indeed, I am persuaded that nine-tenths of the cases of hæmorrhoids that we meet with could have been cut short by the timely and vigorous application of the local treatment here recommended. Cold water I never direct to be applied, believing it to be positively harmful. As Dr. Emmet says, "cold is a prompt exciter of reflex action, by which the vessels are made to contract, but on reaction taking place, the parts will become more congested than before, both the arteries and veins being distended." After the hot water the parts are to be wiped dry with a soft towel, and the vaseline compound to be well applied to the external and internal surface, halt as far up as the index finger will reach. Nothing I have ever applied has so soothing an effect as the sulphur and vaseline, and if done in the morning upon first getting up, it promotes an easy evacuation from the bowels soon after breakfast. I should state here that I have used the vaseline without the sulphur, and that the results were not so satisfactory.

I well remember when I was a student of medicine in what haphazard way the old ung. stramonii was employed in every case of piles that came along, regardless of the varying pathological states to which they might be incident. Besides, nearly all the old salves, ointments, etc., under favorable conditions of heat, are subject to chemical change and become rancid. By this process the fatty acids are set free and become an irritant to any sensitive surface. Vaseline undergoes no such change, but will remain upon the part indefinitely without alteration. I have thus briefly touched upon some points regarding the subject of hæmorrhoids, which I think are not universally considered, and I have been led to do so by the large amount of unnecessary suffering I have seen from this cause. A large part of this, as I have said, I believe can be averted by very simple measures in their earliest stages, and when further advanced, permanently relieved, without danger or detriment to the patient, by a scrutinizing investigation into their exact pathological features, upon which alone can be founded a rational mode of treatment, the outcome of scientific principles.

FORT STOCKTON, TEXAS, June, 1882.

THE POWDER OF THE PYRETHRUM, or common insect powder, is recommended very highly for *pediculus pubis*.

PURULENT CYCLITIS FROM SEPTIC EMBOLISM OF THE EYE, IN A CASE OF PHLEGMONOUS ERYSIPELAS.

By HENRY G. CORNWELL, M.D.,

COLUMBUS, O.,

CLINICAL LECTURER ON OPHTHALMOLOGY AND OTOLOGY, STARLING MEDICAL COLLEGE, COLUMBUS, O.

Miss L——, aged thirty-two, brunette, of Youngstown, O., was, about April 1, 1880, attacked with facial erysipelas of idiopathic origin, which soon after assumed a phlegmonous type. Two weeks later her physician, Dr. Matthews, asked me to see her for an eye disease which had developed four days before.

On examination the lower part of the face of the patient was found to be much swollen, and at a point on the left side, where the mucous membrane of the lips joined the integument, some pus escaped. The lady had for some years been the subject of dyspepsia, which exhibited itself in an obstinate irritability of the stomach, together with nausea and vomiting, since the development of the erysipelas. The sight of the right eye became impaired four days previous, attended with pain and photophobia when it was exposed to light. Examination revealed lids somewhat swollen, circum corneal injection, tenderness in ciliary region, no chemosis, cornea clear, an hypopyon about three millimetres in depth, iris of normal lustre, pupil moderately contracted, responding slowly to light and to a four-grain solution of sulphate of atrophia, which caused it to dilate to about one-half the size that would be obtained in a healthy eye. T.—2, vitreous cloudy, so that the fundus of the eye was not revealed on ophthalmoscopic examination. Vision, ability to count fingers at five feet. For this condition a four-grain solution of atrophia was used every three hours, and cloths wrung out in hot water applied to the eye after varying intervals, for as long a time as the strength of the patient would permit. The treatment for the erysipelatous disease was stimulating and supporting in character. Two days later the circum-corneal injection was less intense, and the hypopyon diminished in quantity. Vision, ability to count fingers at two feet; eye tension same as before. Three days later the hypopyon was almost entirely gone. The other conditions were the same. Two days later the injection in the ciliary region was limited to the upper half of the periphery of the cornea. Tendernesss in this region manifested on pressure; pupil partially dilated by the atrophia solution; no adhesions of the iris to the lens; pupillary space circular and filled with rich yellow pus; small hypopyon. When the patient was raised from the dorsal recumbent position, the pus escaped from the pupillary space and formed an hypopyon of considerable depth. Globe very soft. Vision, perception of light. No marked changes were exhibited in the erysipelatous affection during the time the condition of the eye was under observation, except that the discharge from the lip ceased after the fourth day. The left eye remained unaffected. The patient died from exhaustion April 24th, two days after the last noted eye symptoms were observed.

Septic embolism of the eye is very rarely observed. Its etiology was first discovered by Virchow in 1856 (*Arch. für Pathologische Anatomie*, bd. ix., p. 307, and bd. x., p. 175). This observer pointed out the fact that panophthalmitis could have its origin in embolic obstructions in the circulation in the vessels of the choroid or retina, due to the entrance of septic material into the blood. A further consideration of the etiology of the condition will be given in the latter part of the paper.

The conditions which have this form of eye disease as a complication are manifestly various. First in point of frequency may be noted puerperal diseases, the whole number of which reported exceeds that of all other conditions put together. Of the forty-eight histories of cases from all causes I have before me, the eye inflammation was due to puerperal disease in thirty (Virchow's,[1] Hall and Higginbottom's,[2] Mackenzie's,[3] Martin's,[4] Hirschberg's,[5] Knapp's,[6] Hosch's collection,[7] etc.). In the others the causes vary as follows: Ligation of varicose veins,[8] ligation of carotid for aneurisms,[9] diffuse cellulitis of forearm,[10] phlegmasia dolens,[11] boil on opposite cheek,[12] after amputations,[13] crushing of leg,[14] pulmonary tuberculosis,[15] suppurating tumor of the neck,[16] suppurative cystitis after tabes,[17] suppurative inflammation of fingers,[18] removal of hymen,[19] amputation of *cervix uteri*,[20] retained placenta,[21] and facial erysipelas.[22] Of these forty-eight cases thirty-nine died. Of thirty-four cases, in twenty-nine both eyes were affected, and of these only two lived.

The terms "metastatic choroiditis," "metastatic uvitis," and "metastatic irido-choroiditis," often used, are, it seems to me, incorrectly applied to this disease, since it has been ascertained that other parts of the interior of the globe—the retina (Meckel, Hirschberg) and the iris (Leber, Landesberg)—may be the starting-point of the suppurative process. Hirschberg very clearly puts the views of most observers in the following paragraph ("Puerpural Septic Embolism," *Arch. of Ophth.*, vol. ix., No. 4, p. 382. Vide also Knapp's cases of simple choroidal embolism, *Arch. of Ophth.*, xiv., 1):

"Simple embolism of a retinal artery causes instantaneous blindness of the eye affected, with the well-known ophthalmoscopic picture (thread-like retinal arteries, gray œdema of the retina, produced by optical contrast) and terminates in atrophy of the optic nerve and retina. Septic embolism, whether of a retinal or choroidal artery, causes rapid disturbance of vision, usually accompanied with immediate haziness of the fundus oculi, and terminates in purulent inflammation of retina, vitreous, choroid, iris, etc. Septic embolism of a very small branch may leave a remnant of vision for a few hours, or even days, until suppuration gains the upper hand in the fundus oculi, and total blindness ensues.

[22] Author's case.

Simple embolism of the same branch could not, perhaps, be diagnosticated."

The term "puerperal septic embolism of the eye" is manifestly too narrowly applied, since the suppurative disease bears the same character after different causes.

The case I report differs from the other on record in the form of destruction of the globe. It was not a violent inflammation with marked chemosis, ciliary pain, exudations into pupillary space, swelling of the lids, total loss of sight, etc. But was insidious in its development and progress, the eye retaining vision, which at its worst was sufficient to distinguish readily between light and darkness. Its prominent features were, at first, ciliary injection of moderate intensity, clear pus in pupillary space, together with slight hypopyon, cloudy vitreous, extreme softness of the globe, the cornea and iris not involved.

I am inclined to the opinion that, in this case, the embolic plug found a lodgement in the ciliary body, the suppuration extending backward to the choroid later in the progress of the disease.[1] The elements on which this opinion is founded are:

First.—The vision; ability to count fingers until within a few days before death. With a few exceptions, in the reported cases of this disease, all perception of light was lost very early in the course of the affection. Hirschberg notes exceptions in the last lines of the above quoted paragraph, but it seems to me that these are not applicable to this case.

Second.—The extreme reduction of the globe tension, not attended with other evidences of violent purulent inflammation, viz.: chemosis, severe circum-orbital pain, swelling of the lids, etc., together with the sight as above recorded.

Third.—The formation of so great a quantity of pus that when the patient was lying on her back it filled the pupillary space and formed an hypopyon.

We can imagine a purulent inflammation to have its starting-point in this part of the eye, due to obstruction of a vessel by a septic plug, exhibiting the features noticed in this case, the pus being poured into the posterior chamber from the free ends of the ciliary processes; the nutrition of the vitreous suspended, together with a reduction of the volume and the formation of opacities in that body; the sight being more and more impaired, together with a corresponding lessening of the ciliary injection as the disease extended back to the choroid. It might be said, on the contrary, that attending purulent cyclitis might be expected; tense chemosis, pain, etc., which were not present in this case. However, it is very evident from what we observe in this case that suppuration can go on to a considerable degree in eyeball without chemosis, pain, etc., and if such a condition could occur in the choroid or retina without chemosis, ciliary neuralgia, etc., why, supposing the suppurative disease to have had its origin in one of these situations, not in the ciliary body? Clinically we know but little of primary suppurative cyclitis. Where it follows plastic cyclitis, either idiopathic in its origin, or when due to injuries from foreign bodies, etc., its course is manifestly modified by the injury or the form of the inflammation it succeeds. Alt says:[1] "Raab at a recent date thought that in a case of purulent panophthalmitis described by him, the origin of the affection was to be found in the embolism of a ciliary blood-vessel. This, I think is, for obvious reasons, highly improbable, and has not been observed by others." Why for "obvious reasons" the author regards such a condition highly improbable is not clear to my mind. He presents no arguments to controvert such an hypothesis.

In the case I report the cornea and iris were unaffected. The lids were at all times somewhat swollen, but this was due to an extension of the general swollen condition of the face; no evidences of orbital cellulitis were at any time present.

The germ theory has recently entered conspicuously into discussions on the etiology of this form of eye disease (Heiberg, Litten, Hosch, Hirschberg, and others). Hirschberg writes:[2] "Whoever searches for emboli of the retinal vessels under the above-named circumstances, must remember that the embolic material consists of *bacteria*—of a mass which has been swept away from any given portion of the body into the veins, has passed the capillaries of the lungs, and then been driven onward by the arterial current into any given portion of the body. The embolic nature of the intra-ocular process was demonstrated twenty years ago by Virchow, lately confirmed by Roth, and the bacterial embolic material recognized by Heiberg and Litten. But little weight is to be attributed to a few negative conditions, chiefly in the later stages of the disease, because it is then so difficult to prove the presence o bacteria."

It seems to me we must accept such statements, *cum grano salis*, inasmuch as our opinions on this subject are not clearly settled. It is true that the presence of bacteria enables us to explain how certain results are obtained which we cannot otherwise easily account for; but the whole question still remains a debatable one. In Hosch's case[3] micrococci were discovered in the retina and vitreous body, but it is not clear to me that the *infarction was due to bacteria.* It is possible that the stasis in the circulation, due to the embolic plug, favored the development and multiplication of the germs. Horvath has demonstrated[4] that these germs do not multiply in rapidly moving fluids, and that when discovered in certain conditions in the blood they were found only in the capillaries and veins, and also in the lymphatics, where in a state of health the flow is about one-fifth slower than in the arteries. All the different forms of these germs, moreover, are smaller than the blood-corpuscles, and much more so than the lumen of the capillary blood-vessels, so that it is difficult to see how infarctions from their accumulation can take place.

Septic inflammation of the eye has been observed in variola, scarlet fever, cholera, rheumatism without heart complication, and after malarial poisoning, to the development of which latter conditions the bacteria in the blood is attributed. Landesberg records a case[5] where such a condition was established in what was believed to be intermittent fever, in evidence of which opinion the spleen was enlarged, the intermittent character of the disease was ob-

[1] It seems to be pretty conclusively settled that the vitreous humor, as well as the aqueous humor, is secreted by the ciliary body. At all events the choroid and iris can be excluded from having much to do in this process. Glaucoma: Its Causes, Symptoms, Pathology, and Treatment. served, together with its rapid disappearance on the administration of quinine. The patient died some months later from what was supposed to be metastasis of the brain and lungs.

How important a *rôle* germs play in bringing about such conditions, with our knowledge of the subject, I think it might be fairly said, is uncertain. Magnin says,[1] concerning the influence of bacteria in putrefactions, fermentations, surgical lesions, contagious diseases, etc., that "notwithstanding the considerable numbers of labors of which the bacteria have been the object, in these different points of view it is not yet possible to define it in a certain manner."

Progress of Medical Science.

Syphilitic Azoospermism.—In the June number of the *St. Louis Courier of Medicine*, Dr. J. P. Bryson relates several cases of sterility in the male, resulting from syphilitic infection. The author points out that the agency of syphilis in the production of sterility in men, has been very generally overlooked, or else is only very briefly referred to. He accounts for this fact partly on the ground of the prevalent belief that, a man who is potent is not sterile, but mainly for the reason that patients are vastly more concerned about their copulative than about their procreative powers. The knowledge that the testes are not necessary to life, nor even to the maintenance of a perfect state of health, he believes to be perhaps responsible for the neglect on the part of investigators to study more closely the influence of various diseases in the production of azoospermism. In none of the cases described by Bryson had there even been noticed any enlargement of the testes, nor could any one of the patients remember that any pain had been felt. The pathological basis of syphilitic azoospermism is held to be an interstitial connective tissue process, which secondarily affects the epithelium of the seminiferous tubules. In the end, a true fibrous degeneration of the organ ensues. It should be remembered, however, that this is a theoretical inference devoid of actual substantiation by microscopic examination. According to the author azoospermism may be due to:

1. Congenital bilateral deficiency of the epididymis or vas deferens.
2. Congenital bilateral anorchidism.
3. Cryptorchidism.
4. Affections (diseases) of the testes.
5. Obliteration or obstruction of the epididymis or vasa deferentia.
6. To abnormal (diseased) conditions of the semen.

He concludes by remarking that, so long as there remains even a modicum of healthy epithelial structure in nervous connection with the centres, even though it is utterly incapable of forming zoosperms, there seems to be no danger of impotence, though sexual capacity may be materially impaired. The sperm forming power of these cells is not necessary to the existence of that influence which they have on the sexual nervous system and which so closely resembles that of the ganglion on the posterior roots of the spinal nerves. So azoospermatics are not sailing on so narrow a margin of potency as one would imagine at first blush. In all the cases recorded by Bryson, treatment was ineffectual in restoring the testes to a normal performance of function, and the prognosis of syphilitic azoospermism would, therefore, appear to be invariably unfavorable.

Effect of the Rheumatic Diathesis upon the Initial Lesion of Syphilis.—That the course of syphilis may be greatly influenced by any so-called diathesis of the patient, is well known to all careful observers. Dr. Lockwood (*British Med. Journal*, May 27, 1882) records a number of cases which would seem to show that rheumatism may very decidedly influence the course of the initial sore of syphilis.

The following is typical of a number of similar cases reported by him:

A patient, aged twenty-six years, came under Dr. Lockwood's care in September, 1879. He had what appeared to be an excoriation near the frænum. Ordinary applications had no effect upon it. By the end of September the sore was larger and considerably indurated; not inflamed or particularly ulcerated. The inguinal glands were indurated. About the beginning of October the character of the sore changed. It became inflamed, very painful, and excavated. There was a profuse, thin, and slightly sanguineous discharge. Small sloughs occasionally separated, and the ulceration extended until about a quarter of the glans penis was destroyed. The appearance of the disease at this time was quite characteristic. The sore was acutely inflamed and phagedænic. In November there was acute inflammation of the dorsal lymphatics of the penis, with roseola over the chest and belly. The treatment adopted locally, during the whole course of the disease, was the use of warm baths and the application of iodoform. Constitutionally, two and a half grains of blue pill were administered night and morning. The effect of mercury was to cause the sore to spread, and increase the pain. Iodide of potassium with tartrate of iron was given in increasing doses. Opium was administered to relieve the pain. Improvement was rapid and continuous, and the sore healed. Afterward, the patient had a slight tubercular syphilide and ulcerated throat. These were relieved by increased doses of iodide of potassium (thirty grains) three times a day, and calomel vapor baths (fifteen grains) every other night. About February, 1880, he discontinued the iodide of potassium, and took half a grain of green iodide of mercury each night for a few months. He is at present free from symptoms.

In this, as well as the other cases, there was a clear history of antecedent rheumatism, and the author thinks that, even if not positively convincing, they are at least eminently suggestive. He concludes that, in cases of syphilis, in which the initial lesion is inflamed and phagedænic, and in which there is a history of rheumatism, it is probable that iodides will be of service at an earlier stage than usual. Mercury should be administered with the greatest caution, if at all.

Diabetic Endocarditis.—M. Lecorché points out, in a communication to the Académie des Sciences, that the frequent occurrence of inflammation in the course of diabetes leaves no doubt of the tendency of this affection to produce in the persons who are attacked by it an inflammatory diathesis. The inflammations are not confined to the skin, the digestive canal, the kidneys, nor the lungs; they may implicate other organs. M. Lecorché recently described to the Academy of Medicine, as one of

the somewhat frequent complications of diabetes, atrophic cirrhosis of the liver. He now draws attention to endocarditis. Diabetic endocarditis, which he has observed on several occasions, appears to show itself more frequently in females than in males (in eight cases out of fourteen). He has not met with it otherwise than in the chronic condition, and only as a complication of subacute or chronic diabetes. It only appears at an advanced stage of the disease—two or three years, or even more, after its commencement. Its appearance seems to be favored less by the intensity of the glycosuria than by its long duration. It is localized at the level of the mitral orifice, and M. Lecorché has only seen it on one occasion situated at the level of the aortic orifice. It reveals its existence by a *bruit de souffle* with the first sound at the apex of the heart, and by irregularity and intermittence of the pulse. It is sometimes accompanied by atheromatous degeneration of the arteries (twice out of fourteen cases). It accelerates the progress of diabetes, and frequently brings on death, either by inducing a more or less generalized œdema, ascites, or by becoming complicated with acute hepatitis. It seems to be due to the irritation which the prolonged contact of blood, changed by the presence of sugar in excess, produces on the lining membrane of the heart.—*British Medical Journal.*

Effects of Smoking on the Heart.—Cases of intermittent pulse have often been observed, in which the cause was unquestionably the use of tobacco, the difficulty disappearing in almost every instance where the habit was abandoned. The *Sanitary News*, under the head of "Danger Signals," presents the following interesting facts on this subject:

"Some years ago M. Decaisne drew attention to the fact that tobacco-smoking often causes an intermittent pulse. Out of eighty-one great smokers examined, twenty-three presented an intermittent pulse, independent of any cardiac lesion. This intermittency disappeared when the habit of smoking was abandoned. He also studied the effects of smoking on children from nine to fifteen years of age, and found that it undoubtedly caused palpitation, intermittent pulse and chloroanæmia. The children, furthermore, became dull, lazy, and predisposed to alcoholic drinks. Recently he reported to the Société d'hygiene (*Gazette Obstétricale*) the results of his observations on the effects of smoking on women. Since 1865 he has met with and observed forty-three female smokers. Most of them suffered from disturbances of menstruation and digestion, and eight presented very marked intermittency of the pulse without any lesion of the heart. He gave detailed accounts of these eight cases, in which all treatment directed against the intermittency proved utterly useless, while the suppression of tobacco was invariably followed by improvement and very often by complete disappearance of the phenomenon."

Aural Vertigo.—In a paper read before the Philadelphia County Medical Society, Dr. C. H. Burnett presented the following conclusions on aural vertigo:

There are two sets of fibres in the auditory nerve, viz., the sensory and the motor.

The motor filaments are connected on one side with the cerebellum by means of the inferior peduncles, and on the other side with the nerve-filaments sent to the ampullæ of the semicircular canals.

Irritation of these ampullar nerves may be conveyed from either of the three parts of the auditory apparatus, or from the auditory nerve itself, in the mechanical form of pressure, and this irritation may be further conveyed to the cerebellum and cause vertigo; so that it logically follows that this reflex cerebellar phenomenon as produced by aural irritation should receive the general denomination of *aural vertigo*, and that Ménière's disease is only a form of aural vertigo. Hence the latter name, unless used after accurate diagnosis of a disease originating in the labyrinth—*i.e.*, in the semicircular canals—will create confusion. But it should be said, in justice to Ménière, that, so far as the writer knows, he has never claimed a general application of his name to all forms of aural vertigo. It has been so applied only by well-meaning but inaccurate diagnosticians.—*Philadelphia Med. Times*, June 3, 1882.

Nicotinic Amblyopia.—Dr. Miguel Segura, in an article published in *La Clinica de Málaga*, concludes as follows: The amblyopia of alcohol and that of nicotine have many points of resemblance, but also differential characteristics, which may be thus summarized. The pupil is dilated in alcoholic amblyopia, and contracted in the nicotinic form. The beginning of the former is sudden, almost instantaneous, the course of the latter slow and progressive.

In alcoholic amblyopia both eyes are equally affected, while in the nicotinic form one or both organs may be involved, generally, however, one later than the other, or unequally. In alcoholic amblyopia the patients see better at night, a bright light disturbs them, they complain of chromatic phenomena, and of disturbances due to spasms of the muscles of accommodation. Those suffering from nicotinic amblyopia, however, see better during the day, and do not observe the other phenomena named. In nicotinic amblyopia the basis of treatment is the enforcing of complete abstinence from tobacco.

Recovery is expedited by tonics, hypodermic injections of strychnine, and by caffeine; the last named increasing the activity of the circulation, overcomes the stupefying action of tobacco by thus exciting the nervous centres. Sulphate of quinine and bromide of potassium specially recommended by Italian ophthalmologists, have yielded brilliant results, especially in the mixed amblyopia of alcohol and tobacco.

The Value of Abnormal Respirations as a Sign of Incipient Pulmonary Tuberculosis. — M. Grancher, in a communication to the Société Médicale des Hôpitaux upon the above subject, concludes as follows: In view of the importance of arriving at the earliest possible diagnosis of tuberculosis, great value should be placed upon abnormal respirations. When they are limited to one apex, especially to the left, these abnormal respirations do not alone aid one in making a diagnosis, but are of themselves sufficient to establish it without any modification of sound, and without adventitious signs, crackling râles, etc. These abnormal respirations are, in the order of importance: rude and low-pitched inspiration, interrupted respiration (*respiration saccadée*), and feeble respiration. These conclusions are not applicable to patients who have previously suffered from general pleurisy, from pneumonia, or from any other grave disease of the lung or pleura. On the contrary, they are of the greatest value in young folks suspected, for some reason or other, to be subject to a tubercular process.—*La Tribune Médicale*, June 25, 1882.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, August 12, 1882.

HOW TO CONSULT.

At a recent dinner of prominent medical gentlemen in this city the conversation settled itself in a purely natural way upon the subject of the ethics of consultation. Many matters of personal experience were recited, illustrating almost every possible phase of relationship of attending and consulting physicians, and withal there was that general freedom in the interchange of opinion regarding mutual rights and obligations which is not uncommon on similar occasions of prandial association. It is quite possible that the discussion was flavored with more of seriousness than is customary at such times, for each seemed to feel that the topic was one of more than general interest, that it presented many sides for consideration, and was of a scope to compass the greatest interest of the entire profession. It is not our purpose to rehearse the doings of this interesting company in any detail, but merely to allude to some general principles which are quite reasonably based on many of the facts presented. At least, enough material was furnished on the occasion referred to to serve us in good stead as ready food for much reflection.

We are, perhaps, prepared now to present the divisions of the subject in our own way, and draw such conclusions as may seem legitimate from the premises. For the latter, we throw ourselves mostly upon the experiences of the little company of diners at the Union League.

In considering the obligations of all parties concerned in a consultation, we shall, for the sake of convenience, make three divisions of the subject: first, the rights of the attending physician, those of the consultant, and lastly and most important of all, those of the patient.

The rights of the attending physician are pretty well settled by common usage. It is generally understood that a consultant is called in to endorse, if possible, the treatment of the attending physician, and in every possible way to strengthen the latter in the confidence of the patient and his friends. This is a good rule, and generally is easily followed in the interests of all concerned. No man can be party to any consultation against his will. If he selects his own consultant he does so because he believes the man of his choice to be the one capable of giving advice; if he consents to meet another who may be named by the patient, he does so with a full knowledge of his privilege of objecting to such consultant for any reasonable cause. Hence the mere meeting of a man in consultation by a general practitioner, implies an understanding to look after each other's personal and professional interests. It is not difficult to understand why the general practitioner who agrees to meet a consultant, has a decided advantage in the way of protecting himself from criticism, which may have the slightest suspicion of an unfriendly turn. Unless some such guarantee were given to the family attendant, consultations would be few and far between, and when they were held, might not infrequently result in disgraceful scenes in the sick room. At least, the exhibition of trivial differences of opinion are guarded against, and every effort is made to keep alive that abiding faith in the good and long-trusted family attendant, which faith is always more than half the battle against the disease. This is as it should be, and the general line of conduct to such an end admits of no change for the better. The family physician honors the consultant by an implied confidence in his judgment, and the consultant is bound in turn to do everything in his power and with a perfectly unselfish spirit to reciprocate.

It is seldom that the family attendant is disposed to take any advantage of the situation. And this leads us to the consideration of the personal rights of the consultant as compared with those of the regular attendant. If the latter assumes too much, must the consultant, out of courtesy, yield? Certainly not. But the contrary is so often the case, every one knows.

The sentiment of the little company into whose confidence we admit our readers, was distinctly to the effect that the business of being called in merely to endorse another's practice, good or bad—and oftentimes the latter—was being carried in some quarters, too far. The consultant was in such cases a convenient figure-head, behind which the little mistakes of the family attendant were quietly hidden. If these mistakes were trivial in character, or merely founded on personal differences of opinion on unimportant points, and really worked no harm to the patient, there should be no concern one way or the other. The duty of the consultant was plainly on the side of his confrère. Should, however, a

radical opposition to each other's views exist, there was a conscientious reason why a statement to that effect should be made to the friends of the patient, and if necessary a third consulting party be chosen. Before the patient the opinions of each are entitled to an equal amount of respect, but between themselves the consultants may concede one to the other, according as either may have more extended experience or greater skill. Thus, it was declared to be absurd for a family practitioner to question the judgment of an ophthalmologist upon the propriety of operating for cataract in a given case, or to place himself on a par with an acknowledged expert in any particular department. And yet cases were cited in which the latter course was boldly taken by gentlemen who obviously knew not the responsibility they were assuming. It was hardly to be expected that the specialist under such circumstances would retire from the case without a free and courteous expression of difference of opinion.

Regarding the relations of consultants to patients, much was said by the diners in a semi-confidential and off-hand way. By some consultants it was said to be the practice of communicating with the physician in attendance only. So far as such might be in the light of a strictly medical consultation and the discussion of technical points connected therewith, it was eminently proper, but was thought to be unjust to the patient or his friends to deny either the right of a formally expressed opinion from the consultant. The patients pay for such an opinion, and consequently have a right to it. Otherwise patients could consider that consultations are, as a rule, a farce, and only benefited the doctor in attendance, who virtually had the thing his own way in any event. And this was really one reason why it was believed that consultations were falling into disrepute among many of the more cultivated classes. The important points to agree upon were those of diagnosis and prognosis, save in exceptional cases, requiring the exercise of special skill, as in operative procedure and the like. The details of treatment was generally left to the attending physician, who was, of course, willing to receive suggestions. Open discussions before the family upon technical points, or the offering of reasons for any slight difference of opinion between the consulting parties were always dangerous, giving the audience anything but the proper faith in medicine as a science. Patients who want opinions like to have them positive in character. They at least think that the given factors, patient, doctor, and treatment, are always constant in their relations, and that there are reasons almost mathematical why a correct diagnosis should be made, the proper treatment selected, and unerring prognosis given. The nearer we can approach this ideal by a distinct agreement on all the necessarily cardinal points, the more positive concerning them we can appear to be to the patient, the better for all concerned.

It had very properly grown into the fashion, at least in attendance upon the higher classes, for the consultant to deliver the opinion to the patient's friends, and in the presence of the family physician. Hardly a case could be imagined in which such a course was not proper. The family attendant obtains all the benefit possible in the consultation by private discussion in the adjoining room. If an agreement is arrived at, either as to the necessity of changing the treatment or not, it is a simple matter to say so afterward to the patient's friends, making the decision a joint transaction in which one party to it cannot in any event obtain undue credit over the other. The statement of general conclusions is sufficient, immediately after which the consultant should leave the patient with the latter's regular family attendant. When there is a radical difference of opinion, the fact can be stated in much the same manner, without in any way reflecting on the judgment of either party, or of the right of each one to his own convictions. Then there is nothing hidden, no reflections are cast on any one, the consultant conscientiously earns his fee, and the patient and his friends are satisfied. All satisfactorily done when the right men meet.

At this stage the conversation is more or less desultory; one gentleman cites a case in which a physician had treated a lady for enlarged inguinal gland, when the swelling was really due to a dislocation of the femur of the pubes. Bad case, that, but nearly equalled by other similar mistakes in diagnosis within the experience of those present.

"But how do you treat office patients who come for an opinion," is asked across the table. The answer summarizes itself from different points of view. If the physician comes with his patient, then a formal consultation is held; if the patient is sent by the physician the opinion is given to the latter under seal, but as is becoming the custom, when the sick one asks for an opinion on his own account, usually regarding the propriety of an operation, and reserves a right to choose from a multitude of councillors, he obtains what he pays for, nothing more and nothing less. And all agreed that these were the proper positions to take.

THE CARE OF EMIGRANTS.

A BILL has been favorably reported by the House Committee on Commerce, aiming to regulate the carriage of passengers by sea. It has been carefully drawn and is approved by the steamship companies. It contains provisions for the sanitary care of emigrants which may have some interest to the profession. Indeed it has been largely by the advice and at the urgent promptings of medical men that the

reforms proposed in this bill have at last taken definite shape.

The bill provides that one hundred cubic feet of space shall be allotted to each passenger on the main deck or first deck underneath, and one hundred and twenty cubic feet for those in the second deck below the main deck.

The height of the ceilings must be not less than six feet.

There must be only two tiers of berths, which are to be not less than six feet by two in the case of single berths. Only one person above the age of eight is allowed to sleep in a single berth. Children under one year are not counted, while two children between the age of one and eight years can be reckoned as one. Provisions are made also for the separation of the sexes.

There must be two ventilators for every fifty persons.

The water-closets must be numerous, viz., one for every one hundred males and two for every fifty females.

Directions are very explicit as regards the amount and the serving of the food. The equivalent of at least one and a half navy rations must be supplied to each person, and meals must be furnished regularly three times a day. Two apartments for use as hospitals are to be provided. These must have at least eighteen superficial feet for each fifty passengers. A qualified surgeon is to be in attendance. Periodical cleaning and disinfection, if necessary, is to be enforced. Prohibition is made against the carriage of dynamite or other dangerous compounds and also against the carriage of animals in a way or to an extent likely to discommode passengers.

Proper arrangements are made for the examination of the passengers by the health officer when the vessel enters port.

If the bill, thus carefully drawn, becomes a law, as it should do, we shall hear less of the horrors of emigrant ships now periodically published.

GERMAN WATER-CURES.

THE prominence of baths and mineral waters in German therapeutics is very noticeable. Large works, like Ziemssen's, are devoted to Balneology alone. This fact is due, in great part, certainly to the large number of medicinal springs to be found in that country as well as in Austria and Hungary. It has become very much the fashion for city people of the continent to go to some springs for the summer and there recuperate. The question, says a German author, presents itself every summer to the invalid and to those exhausted by winter's work or gayety, "to what bath shall I take my enlarged liver, my unhappy stomach, or my deranged nerves?"

Dr. Kämpf, in the *Badearzt*, attempts to answer this query, in part, and gives an entertaining sketch of some of the health resorts of Austro-Hungary.

Carlsbad is placed at the head of the list. Liver troubles, gravel, obesity, diabetes, catarrhs of all kinds, will, we are assured, disappear entirely, or to a great extent, under the beneficent influence of its waters. Marienbad has a very similar reputation.

Franzenbad is a curious place and very different from the former. It is visited almost entirely by women. Those who are suffering from the effects of child-birth, who are worn out, feeble, and anæmic, go to Franzenbad and drink its chalybeate waters.

The number of hot sulphur baths, which are reputed valuable for skin diseases, rheumatism, and gout, is quite large. It includes Trenezin-Teplitz, Pystian, Warasdin, Gastein, the Brennerbad, and Neuhaus, which latter place has also a reputation for nervous diseases. Most of the above places are frequented chiefly by invalids, and are rather dolorous spots for those who are not very ill and wish amusement as well as medicated water. For this latter class such places as Baden-Baden, Wiesbaden, Hamburg, Giesshübler, etc., are especially adapted. The waters of the last named place are recommended as among the most pleasant to the taste of all.

Patients with chronic skin diseases choose either the indifferent thermal or the sulphur baths. Dr. Kämpf asserts that, in his opinion, the most efficient waters for these diseases are those of the Bad Lenk in Switzerland. He speaks in particular of its effects upon psoriasis.

Scrofulous patients and those suffering from venereal disease go to Hall, Luhatschowitz, Lipik, etc. Also to Schroth's Hunger or Breadcure in Lindewiese. This Schroth was originally an ignorant peasant, who conceived a theory of disease and based upon it a system of treatment which made him widely famous. He deprived his patients of food almost entirely, giving them only an occasional piece of bread and drink of wine. They were sweated and purged at the same time. When he had sufficiently reduced them, and the "materia peccans" was driven out, he fed them freely again. His results were very brilliant, especially in some bad forms of syphilis. Priessnitz, "the discoverer" of the cold-water treatment, for a long time carried on a rival establishment at Gräfenburg.

The Tyrol has as many as fifty-five different medicinal springs. None of them are much developed, however. There is an average of half a dozen patients living near each. One of them, at Roncegno, contains a little arsenic.

Some of the mineral waters are reported to have certain fecund properties; for example, the Bubenquelle at Ems. How much they deserve the reputation is not said. But sterile women go there, and are satisfied.

The above somewhat random facts may serve to remind American physicians that we have mineral waters also which are probably quite as good as those of Germany. Their actual medicinal value, however, has not been studied carefully and impartially to any extent. But we might profitably utilize our "water-cures" to a greater extent than is now done.

Reviews and Notices of Books.

MEDICAL AND SURGICAL REPORTS OF THE CITY HOSPITAL OF THE CITY OF BOSTON. Third Series. Edited by DAVID W. CHEEVER, M.D., OLIVER F. WADSWORTH, M.D., and A. L. MASON, M.D. 8vo, pp. 390. Boston, 1882.

THE aim of the editors of this volume has been to present such a selection of hospital cases as may be most useful for comparison and reference. They have succeeded so well in their work as to make it a model of its sort, and leave hardly anything further to be desired. The general plan followed has been, as formerly, the contribution of papers on medical and surgical subjects by members of the staff, giving, by way of summary of certain groups of cases, the general practice of the hospital. Such papers have a special value in bringing out the salient points of a large number of cases and utilizing experience in the treatment of disease on a large scale. It is by such means that general principles are evolved and the merits of different methods of managing disease established. The articles contributed are, without exception, well written and to the point, contain material of great practical interest, and give the volume as a whole a special value for the studious and advancing practitioner.

Dr. Samuel G. Webber opens the volume with a painstaking study of the pathological histology of the spinal cord.

Then follow notes of typhoid fever from a series of 1,036 cases by C. Ellery Stedman, M.D. This article partly continues the subject treated by Dr. J. B. Upham in the first volume of these reports. The present record comprises the cases entered on the hospital books for the ten years preceding 1881, and is a most careful study of the history, causes, and treatment, more especially of 192 cases under the reporter's personal observation. The detail of cases is in the shape of corroborative evidence of what is already known concerning the course, treatment, and average results of the disease, and is presented in a terse, practical, and straightforward manner The plan of treatment is mainly supporting, with the incidental treatment of complications. Milk diet is advised in preference to that of beef-tea, as the latter is apt to produce diarrhœa. Above all, the patient is not allowed to contribute to tissue waste by any exertion whatsoever. Thus the author rather significantly and naïvely puts it by saying that diarrhœa requires first the bed-pan. For the reduction of temperature, reliance is very properly placed upon cold baths, sponging, and quinine in antipyretic doses. We are unable to follow the author in his detail of treatment for occasional symptoms and complicating conditions; suffice it to say that it accords with that generally adopted by authorities and mainly practised by the more experienced and leading practitioners.

A rather curious and interesting feature of this volume is a synopsis of fifty medico-legal cases by F. W. Draper, M.D., wherein several examples of death from criminal abortion, from drowning, from accidental suffocation, suicidal wounds, and other modes of sudden death are carefully analyzed.

The surgical cases by Dr. David W. Cheever are interesting and important, and mostly comprise operations about the head and neck. Notably among these may be mentioned an interesting report of a removal of a cancerous tonsil by external incision, and three cases of extirpation of naso-pharyngeal polypi after Cheever's method.

A synopsis of gynecological practice, by Dr. G. H. Lyman, extends over a period of five years of practice in the hospital, but does not present anything more than the ordinary run of cases; neither are any new methods for treating particular affections advocated. Dr. Robert T. Eades' remarks on high-pressure education and its effects are full of suggestions, and deserve careful attention.

The cases of diphtheria occurring in the winters of 1880 and 1881, in the service of Dr. Hall Curtis, are well reported, but, as might be expected, only tell the old story of a given ratio of mortality, no matter what the treatment.

Dr. O. F. Wadsworth contributes an able chapter on optico-ciliary neurotomy, with illustrative cases; and two interesting cases of uterine fibroid are related by Dr. O. W. Doe.

The surgical abstract by Dr. Geo. W. Gay covers a great deal of ground, and includes a summary of the usual cases for operation which present themselves in the hospital ward. Tumors, mostly malignant, are in good proportion. They return as usual after operation, but they are excised and cauterized, nevertheless, in order at least to prolong life and make the patient comparatively comfortable between the recurring periods. We have the typical cases of strangulated hernia, head injuries by gun-shot and other means, plastic operations, etc. The hospital surgeon, by the perusal of these well-observed cases, is enabled to live over many thrilling personal experiences.

Dr. A. L. Mason next gives an analysis of 200 cases of primary pleurisy treated in the hospital during the past ten years. This is made with great care and skill, presenting, in a very condensed and readable form, all the different salient features of the disease. Dr. W. P. Bolles presents some new surgical apparatus, notably a new form of fracture-box and splint combined. It is pretty, and doubtless serves its purpose well, but is rather too complicated to successfully bid for extensive use. His remarks on the tin finger-splints are thoroughly practical.

Dr. E. Wigglesworth and E. W. Cushing give some practical points on the diagnosis and treatment of deep syphilitic ulcerations of the throat, and close the collection. And altogether the volume is one of the most interesting and practical of its kind that we have seen for a long time. Why cannot other hospitals do likewise?

TRANSACTIONS OF THE AMERICAN GYNECOLOGICAL SOCIETY FOR THE YEAR 1881. Vol. VI., 8vo, pp. 542. Philadelphia, Pa.: H. C. Lea's Son & Co.

THE present volume (VI.) of "Transactions of the American Gynecological Society for 1881," while not materially differing in arrangement from the original

plan, is as usual enriched with many interesting essays, presenting in permanent form much original research in the various fields of gynecology not usually embodied in other and more general works. The eminence of the authors affords conclusive evidence of the character of the book, and necessarily adds force to the opinions expressed. Both on this account, and the intrinsic worth which it possesses as a valuable addition to so important a branch of medical study, this volume will doubtless command the same wide attention received by its predecessors.

It comprises twenty essays by the following distinguished contributors: Samuel C. Busey, M.D.; Henry J. Garrigues, M.D.; G. H. Lyman, M.D.; Nathan Bozeman, M.D.; E. Van de Warker, M.D.; Isaac E. Taylor, M.D.; William Goodell, M.D.; Henry F. Campbell, M.D.; T. Gaillard Thomas, M.D.; Thaddeus A. Reamy, M.D.; Albert H. Smith, M.D.; A. D. Sinclair, M.D.; J. W. Underhill, M.D.; Edward W. Jenks, M.D., LL.D.; W. M. Polk, M.D.; Walter R. Gillette, M.D.; C. C. Lee, M.D.; Frank P. Foster, M.D.; E. W. Sawyer, M.D., and B. B. Browne, M.D.

Dr. Thomas' paper on "Expansion of the Bladder over the Surface of Abdominal Tumors and its Attachment to them or to the Abdominal Walls as a Complication of Laparotomy," is especially worthy of notice. The complication is of course a rare one. He reports but seven cases of this character, all fatal, and proceeds with a short history of each, concluding the paper with an account of one recently occurring in his own practice, upon which he operated with success. In his case, which is probably a typical one, there was an enormously hypertrophied bladder spread out over the tumor, extending laterally down into the lumbar regions, and upward to midway between the umbilicus and ensiform cartilage, with extensive vesical adhesions. One very important and practical bearing impressed is the care with which entrance into the abdomen should be effected. The possible diagnosis and management of the complication are then discussed, closing with the views of the author, concerning treatment of the condition.

"Exploratory Puncture of the Abdomen" is the subject of a learned contribution by Dr. Garrigues. As Dr. J. Marion Sims justly remarks, "in importance it is second to none."

Dr. Busey calls attention to a class of cases characterized by pain and tenderness diffused over the abdominal area following upon the introduction of a tent, childbirth, and not infrequently injections, and which he designates by the title of "Acute Diffuse Hyperæsthesia of the Peritoneum." The paper is an interesting one, and many novel points connected with the subject are carefully considered. Much interesting discussion follows, with an instructive analysis of the subject by Dr. Noeggerath.

Dr. Lyman, on "Pelvic Effusion Resulting in Abscess," has presented a paper of great practical value, together with an epitome of forty-one cases which have occurred under his observation at the Boston City Hospital. The attention of the profession is especially directed to the frequency of their occurrence, the importance of their early recognition, and to the propriety of an early operative procedure.

In short, the essays throughout are all of them of an excellence and character which reflects most creditably the depth of thought and experience of the contributars. It is to be regretted that space does not permit further mention in detail of other and equally valuable productions. There are a few plates introduced throughout the work. To it there is also appended an index of the gynecological and obstetric literature of all countries for the year 1880. The volume is, as usual, elegantly printed on fine toned paper, and handsomely bound in cloth.

THE EXPERIMENTAL METHOD IN MEDICAL SCIENCE. Second Course of the Cartwright Lectures of the Alumni Association, College of Physicians and Surgeons, New York. Delivered January 24, 31, and February 7. 1882, by JOHN C. DALTON, M.D. New York: G. P. Putnam's Sons, 1882.

THE above lectures have appeared in substance in THE RECORD, and our readers are familiar with their character and merits. They furnish an admirable *résumé* of the history of the development of the experimental method in science.

THE VEST-POCKET ANATOMIST (founded upon "Gray"), by C. HENRY LEONARD, A.M., M.D. Eleventh Revised Edition. Detroit: Illustrated Medical Journal Co., 1882.

THIS is an unusually good epitome of anatomical facts.

ELECTRICITY IN SURGERY. By JOHN BUTLER, M.D. pp. 125. Boericke & Tafel, 1882.

PRECISION in details on the art rather than the science of operation is the subject of this volume, accordingly we find, under forty separate headings, as many surgical procedures separately and concisely described.

The author regrets the absence of definite dosage in the electro-therapy of the day, and in many instances prescribes his current strength in millimetres to be determined by a galvanometer, and to be controlled by a rheostat. That such accuracy is to be desired is unquestioned; why it is not possible, with similar modifications, for age, sex, and condition which other Materiæ Medicæ require, its objectors do not clearly explain; to have attempted the practice appears to us a step in advance.

The directions are throughout those of a practical worker in the field, and suggest a delicately skilled hand. Of especial interest are the mildness of the surface applications and the extent of treatment the author proposes to accomplish "without pain," in which category his own excellent operation for the division of stricture occupies a prominent place.

While it does not supply the want of a more generalized treatise, this handy little book cannot fail to furnish very valuable hints regarding the management of the current and regarding many ingenious contrivances for their application.

THE PSYCHOLOGY OF THE SALEM WITCHCRAFT EXCITEMENT OF 1692, and its practical application to our own time. By GEORGE M. BEARD, A.M., M.D. 12mo, pp. 112. New York: G. P. Putnam's Sons, 1882.

DR. BEARD is always an entertaining writer. The subject and author are well adapted to each other, and the result is a scientific romance full of interest. The burden of the story is to prove that the hanging of Guiteau, who is adjudged by the author as utterly irresponsible, is on a par with the execution of the so-called witches at Salem; that both procedures were alike the results of ignorance on the part of so-called experts, and prejudice on the part of the public. The theory of Guiteau's insanity is ably defended, and the action of the Government concerning the assassin severely criticised. The pictures are admirably drawn, and the lights and shadows are thrown in with a master hand.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 24, 1882.

DR. E. C. SEGUIN, PRESIDENT, IN THE CHAIR.

THROMBOSIS OF THE UTERINE VEINS.

DR. HEINEMAN presented a specimen, with the following history:

Catharine S——, aged thirty; Ireland; married, housework; a pale woman; pregnant nine months, was delivered of a living male child at the Roosevelt Hospital, May 11, 1882. May 13th, her temperature was 100.8° F. The next day she became delirious, which later disappeared and returned. She had tympanitis, no abdominal tenderness, and finally died unconscious, May 24, 1882.

Her temperature was 104.4° F., her pulse 148°, her respiration 48° on the 17th, and varied subsequently between 102° and 105.2° F., 132° and 160°, 44° and 68°.

On *autopsy*, the heart, stomach, and intestines were found normal. Lungs, slight bronchitis. A small infarction in right lower lobe, surface of lung about infarction coated with recent purulent fibrin.

Liver congested. Spleen soft. Kidneys normal size, capsule not adherent, cortex and surface pale and mottled—parenchymatous nephritis.

Uterus, about natural size for parturient uterus—it presented no lacerations and no portions of retained placenta. Mucus lining of fundus coated with puriform fluid, and the lower portion of the body down to the os internum appeared coated as if by fibrin. Uterine veins all full of thrombi and in the ovarian vein of the right side. Within the broad ligament there was a large firm thrombus distending the vein. The peritoneal surface of the right broad ligament was coated by a little recent fibrin.

ARTHRITIS AND NECROSIS OF RIBS FROM A STRAIN FOLLOWED BY ABSCESS RUPTURING INTO PLEURAL SAC.

DR. HEINEMAN also presented specimens, with history as follows:

Alexander R——, aged forty-four; Scotland; single; stonecutter, was admitted to the Roosevelt Hospital, April 14, 1882. Five years previous to his admission, he strained his right arm and shoulder severely. Four months ago a small swelling appeared just at the lower border of the scapula. This has increased in size and now is sufficiently large to prevent patient's standing up by reason of the muscular tension.

The abscess was opened and evacuated, and washed out with carbolic acid daily.

On May 7th, temperature rose to 102° F. On May 11th, physical signs of trouble in the right chest were recognized, and on May 14, 1882, he died suddenly.

On *autopsy*, the liver, spleen, stomach, and intestines were found normal.

Heart.—Purulent serum in pericardial sac. Surface of heart thinly coated by a little purulent serum. Size and valves normal.

Kidneys.—Chronic diffuse nephritis.

Lungs.—Pleural cavity of right side two-thirds full of purulent serum, right lung covered with purulent membrane and adherent to chest-walls in places; lung compressed and contained a single large infarction—lung-tissue œdematous. Left lung normal except for old adhesions.

Ribs.—Over the neck of the fourth rib there was an irregular opening in the costal pleura which connected with an abscess cavity over the head of the rib posteriorly. The articular ends of the head of the fourth and fifth ribs were eroded, the adjacent lamina of the dorsal vertebræ were necrosed to some extent, and over the neck of the fifth rib, just beneath the pleural surface, a collection of pus, which was nearly ready to burst, was found. Over the posterior portion of the ribs a large abscess cavity communicated with the chest through the opening referred to.

DR. WYETH remarked that the abscess, in the case related by himself at the former meeting, was in danger of opening into the pleural cavity at any moment, and this danger was guarded against by at once incising it. As the patient was yet living, the exact pathological changes were unknown.

DR. N. BOZEMAN presented two specimens:

1, CYSTOMA OF THE OVARY; 2, OVARIAN PAPYLOMA.

The patient was an unmarried woman, thirty years of age, who presented herself to him in February last with an ovarian tumor. Her health was good until four years ago, when this tumor began to develop, although its true nature was not recognized by her physicians until later. There was a fulness in the posterior cul-de-sac, the nature of which was not fully understood, and it was feared that it would render the case less favorable for operation. An attempt was made to improve her general health before proceeding with the operation. On the first occasion she took ether badly, and the operation was postponed until to-day. The cyst had pretty extensive attachments, particularly to the omentum. It contained several smaller cysts. On inverting the tumor, at its lower portion was a papillomatous growth, with cauliflower excrescences. The right ovary was impacted in Douglas' cul-de-sac. Its pedicle was twisted upon itself three or four times, which made it difficult of extraction. It presented a beautiful specimen of small-sized multilocular cyst, the smaller ones being about five in number. By this specimen one could readily understand a certain class of cases of ovarian cyst mentioned years ago by Dr. Atlee. After attaining considerable size the cyst is punctured, and collapses completely. It refills, and the operation may be repeated a number of times, but later without complete collapse. This is due to the gradual growth of the smaller cysts, the fluid of which has no communication with that of the larger one. There was albumen in the urine, and two weeks before the operation her family physician said he discovered granular casts, but other microscopists were unable to detect any.

DR. HOWE remarked that if there were granular casts and albumen in the urine the patient would die. He had never seen a patient with Bright's disease of the kidney recover from a capital operation. It was to be remembered, however, that the presence of albumen alone in the urine was by no means a positive sign of disease of the kidneys, and care, therefore, should be exercised not to make a false diagnosis of renal disease.

DR. L. H. SAYRE remarked that a number of years ago his father exsected the hip-joint of a boy upon whom another surgeon had refused to operate, because of the presence of granular and hyaline casts

in the urine, indicating Bright's disease. The patient recovered from the operation entirely, but died nine months afterward from acute nephritis.

Dr. Gibney remarked that there were cases on record of amputation at the hip or thigh, the patient having amyloid kidney and liver, and recovery from the operation being perfect.

Dr. R. Tauszky remarked that if there were amyloid degeneration of the liver and kidney, uræmic symptoms would almost inevitably develop within a year or two, and the patient die. He was satisfied that an error of diagnosis respecting kidney disease was sometimes made in these cases by mistaking other material, as linen, etc., for casts in the urine. It required a good microscopist to distinguish granular casts in the urine. In certain affections, as scarlatina, casts and albumen in the urine might indicate disease of only a part of the kidney, which might be recovered from.

Dr. Gibney remarked that amyloid degeneration of the liver and kidney was recognized in a boy upon whom it was proposed to operate for amputation of the leg, in Bellevue Hospital, but the operation was desisted from on account of the renal disease. There was albuminuria, and casts had been recognized by two or more able microscopists. The operation was afterward done at the Presbyterian Hospital, and the patient was now well, more than a year since the operation. In that case the liver was recognized as greatly enlarged.

Dr. Howe remarked that it was well known disease of the bones was one of the common causes of amyloid degeneration of the kidneys, etc., and it was not impossible that, after removing the cause in this case by amputation, that it cured the affection of the viscera. If such patients recovered after capital operations, they were exceptions to the rule mentioned, viz., that patients with renal disease almost certainly die after capital operations.

MULTIPLE CEREBRO-SPINAL SCLEROSIS.

Dr. Kinnicutt presented the specimen at the request of Dr. Satterthwaite. It was obtained from the body of a woman who died in his service at St. Luke's Hospital, and the history of the case had been furnished by the house physician, Dr. W. C. Campbell.

Clementia F——; thirty years of age; single; German; was admitted April 27, 1882. When admitted her memory was so impaired that it was almost impossible to obtain a connected history, but as near as could be learned, she was well until two years ago, when she began to have attacks resembling epilepsy. Six years ago she began to have convulsive twitching of the right lower extremity when any attempt was made to walk, and this soon extended to the right arm, and completely incapacitated her for working.

On admission patient was well nourished. Complexion good. No œdema. Complained of no pain. No feeling of cincture and no disturbances of sensation. Her urine dribbled continually—not incontinence, but overflow, catheterization giving relief. Bowels moved involuntarily. There were marked ataxic movements of extremities. No loss of power; marked impairment of co-ordinating power; marked tremor upon voluntary motion, especially of the right extremities, which increased with increase of mental effort; is rhythmical, so great that patient cannot walk. Does not involve the head, and does not exist during rest. Slow, jerky manner of talking, as in "scanning." Tendon reflex normal; marked mental weakness; no irritability of temper; meaningless smile. Pupils react well—right more readily than the left. Diagnosis of multiple cerebro-spinal sclerosis was made. The patient gradually grew weaker; had constant vomiting; no control of sphincters. Mental habitude became more intense daily, till gradually (May 19th) patient ceased to notice anything about her; could be roused, however, and breathing was not stertorous. Urine contained blood and pus.

May 22d.—Articulation very indistinct; deglutition difficult; complexion dusky; listless expression of face; eyes sunken and lids half open. Can still be roused to understand what is said; respiration slow and quiet; tremor of right extremities remains. Apparent paresis of left arm and leg. Reflex skin irritation of lower limbs retained. Heart-sounds normal. Temperature, 99° F. During the night she continued growing weaker. It became impossible to rouse her. Pulse became weaker; respiration, 36; temperature, 102° F. (axilla), and at 5 A.M. patient died. No marked impairment of respiration until just before death.

The diagnosis of multiple cerebro-spinal sclerosis was verified at the post-mortem examination, and constituted the only abnormal condition present.

The President remarked that the affection was not an uncommon one, but we seldom had opportunity to verify the diagnosis by a post-mortem examination. He knew of but one case in this country the pathological anatomy of which was published in connection with the history. The diagnosis in that case had been made during life by Dr. Clymer, and the record was made by Dr. Vanderveer and himself. In reply to a question by Dr. Parker, Jr., he said the original cause of the affection was unknown.

He would add that in some cases where the cerebral symptoms were not marked, as by the presence of nystagmus, dementia, and hallucinations, there appeared to be some difficulty in differentiating between locomotor ataxia and sclerosis in patches, but the condition of the reflexes was, in such cases, diagnostic. In sclerosis of the posterior columns of the cord there was entire absence of the reflexes, while in disseminated sclerosis it was, according to his observation, always present, and usually exaggerated. This was the only differentiating symptom in a certain case which occurred at St. Luke's Hospital.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. W. R. Birdsall reported that Dr. Messenger's specimen—a tumor of the mammary gland—proved to be a carcinoma of the scirrhus variety, consisting of groups of cells, containing considerable protoplasm, and of the type of the neighboring glandular elements, imbedded in alveoli formed by dense bands of connective tissue, the latter predominating, thus accounting for the extreme hardness of the spherical scirrhus mass about an inch in diameter.

Dr. Newman's tumor, removed from the palmar surface of the hand, consisted of true bone, of the cancellous variety.

Dr. L. H. Sayre presented a specimen of

BONE FROM A GUN-SHOT WOUND OF THE FOREARM.

Nearly all the flexor muscles of the right forearm were blown away by the injury. A few days later erysipelas developed. He saw the patient about three weeks later. The ulna was exposed to a dis-

tance of several inches, and the olecranon was also exposed to view. Three or four bony processes projected from the ulna near the wrist joint. An incision was made connecting the openings on the ulna and at the olecranon, when a piece of bone was removed without difficulty. The sinuses below were then divided, a number of pieces of bone were removed, a superficial caries of the radius was scraped, the wound was dressed with oakum. No unfavorable symptom developed, and the patient was now able to be out of doors. The temperature had not risen above 100° F.

CICATRICIAL TISSUE FROM A BURN.

DR. SAYRE also presented a specimen of the above, which was removed from a boy eight years of age, who three years ago sustained a burn covering about two-thirds of the anterior surface of the left thigh and the entire abdomen. The burn originated in the ignition of some phosphorus in his pocket. The wound was about eighteen months in cicatrizing, and soon afterward began to contract in a line from the pubis to the anterior superior spine of the ilium. At the time he saw the patient the contracture had so increased that the thigh was flexed upon the abdomen and abducted, the scrotum was involved, and the penis was drawn to the left side. A band of cicatricial tissue extended from about two inches to the right of the symphysis pubis almost to the anterior superior spine of the left ilium, being about the width of the thumb, and underneath this a similar band. The fascia was not involved. The above bands were dissected out so as to allow of extension of the thigh, and the denuded surface left bare, as it was impossible to do a plastic operation on account of the extent of cicatricial tissue, the limb was retained in the extended position to prevent recontraction. The case was doing well.

DR. RUDOLPH TAUSZKY presented

THE LARYNX, TRACHEA, AND LUNGS, ILLUSTRATIVE OF MEMBRANOUS CROUP.

The patient was a child two years of age, who died of croup of the larynx, trachea, and also extending down into the bronchi of the second division. Tracheotomy had been performed by a surgeon of this city, after dyspnœa had become so great that nothing else would give relief. The child died twenty-four hours later. Dr. Tauszky presented the specimen for two reasons: First, that it demonstrated the difference between croupous and diphtheritic exudation. Here the exudative deposit had fallen off in part of itself, and could easily be wiped off, leaving no ulcerative surface whatever. In the case of diphtheria, however, the exudative deposit could at no time, nor anywhere—from the tonsils, vagina, rectum, or other mucous membrane—be removed without leaving an ulcerative, raw surface. He regarded this distinction between the nature of the two diseases as very important, especially with regard to treatment, and to impress this importance constituted his second reason for presenting the specimen. Recognizing this distinction, it was proper in the treatment of croup to give emetics so as to remove the comparatively loose exudation. Such treatment would be entirely improper in the case of diphtheria, where it would have no effect in removing the deposit, and where a stimulating plan of treatment is indicated even from the beginning. Carbolic acid or salicylic acid should be employed locally as disinfectants, which was not at all necessary in cases of so-called croupous exudation. The distinction between the two affections is well marked otherwise clinically. He had never seen a case of diphtheria in which there was not some enlargement of the lymphatics of the neck; the pulse is weak from the first, and the temperature higher than in croup. A difference between the two affections was becoming more commonly recognized, although there were yet many physicians of high authority who consider them as one.

DR. VAN SANTVOORD said he attended a case of diphtheria this winter in which the pulse did not rise above 80 or 90 per minute until after five days from its commencement. The patient died. There was close attachment of the diphtheritic membrane to the larynx, but lower down it was less difficult to remove.

DR. J. G. PETERS remarked that he had attended a large number of cases of diphtheria where the deposit existed upon the pharynx and tonsils, but in which there was no enlargement of the glands of the neck. In some cases, however, the glandular swelling is very great.

ANEURISM OF THE ASCENDING PORTION OF THE ARCH OF THE AORTA.

DR. WYETH presented a specimen which was removed from a woman on whom he had made the diagnosis of aneurism of the arch of the aorta, at the junction of the ascending and transverse segments, and for its relief had tied the carotid. Before the operation the tumor bulged out beyond the level of the chest at the second intercostal space, but within two weeks after the application of the ligature it had appreciably decreased, and soon afterward was not visible beyond the surface of the chest. The patient died within a year of an intercurrent disease, and at the autopsy his diagnosis was verified. This treatment had been pursued in but five similar cases before, in one by himself. The case also illustrated the safety of the broad ligature. He was unable, satisfactorily, to explain why ligating the carotid should have caused the pain to cease and the tumor to decrease in size, although it was well known to do so in such cases.

DR. W. R. BIRDSALL presented gross and microscopical specimens of

SARCOMA OF THE BRAIN,

in which were found seven distinct neoplasms, ranging from the size of a pea to that of a walnut. The small, round cell or glio-sarcoma type predominated; great variations, however, existed. In portions were found that decided pigmentation of cells characteristic of melano-sarcoma; in others the type of the angio-sarcoma was particularly prominent, in some parts appearing like a series of channels without the definite walls of blood-vessels, producing an extremely vascular condition of the tumor, requiring careful manipulation to prevent extravasation of blood; still other portions of the growth presented a myxo-sarcomatous appearance, also large cells containing daughter cells, presenting a resemblance to the giant cell sarcoma. The spindle cell and fibrin elements were scanty. The most compact portions appeared around the blood-vessels. The margins of the growths were pretty well defined, but not strictly encapsuled, and neighboring parts of the gray and white matter presented a richer development of neuralgia cells than normal. Remarks were made on the effects of their growth on the central functions, and the relation of the facts to the "localization theories."

THE PRESIDENT remarked that a few years ago it was largely believed that tumors of the brain always caused neuro-retinitis or choked disc. This case was one among several which he had seen, in which the ophthalmoscope failed to give corroborative evidence of the brain-lesion.

The Society went into executive session.

MATERIA MEDICA SOCIETY.

Stated Meeting, Thursday, May 25, 1882.

DAVID WEBSTER, M.D., CHAIRMAN PRO TEM.

BEFORE the Society proceeded to the order of the evening, DR. PIFFARD made a few remarks. He stated that he had been asked by a pharmacist to inspect a package of viola tricolor received from a wholesale druggist. Finding in it much extraneous matter, he caused this to be separated and referred it to Dr. Laurence Johnson for examination. Dr. Johnson kindly sent him the following report:

"First and foremost the material consists largely of stubble, *i.e.*, what was left in a field of grain after gathering the crop. This crop was evidently rye, as I find heads of that cereal present. Grass stems and roots are also abundant, and also some flowering stems of the same. Numerous flower-heads of at least two different species of composite plants were also found, and numbers of leaves which could not be identified. One stem of equisetum—mare's tail—pine shavings, twigs, and bark, a few lichens, a shaving of some unknown wood, cut by an auger, a fragment of a tamarind pod with two seeds, an assortment of hempen strings, a plum-stone, a trousers-button, and a specimen of hen-dung are also among the miscellanies found in your precious package."

Dr. Piffard stated that a good fluid extract of this drug could be obtained from Messrs. Caswell, Hazard & Co., of New York.

INDIGENOUS REMEDIES.

The paper of the evening, entitled "Indigenous Remedies," was then read by its author, DR. JOHNSON, who supplemented it by exhibiting a variety of fresh medicinal plants gathered at Woodside, Long Island, a locality exceptionally rich in a number of species. Among the specimens shown were skunk's cabbage, the sambucus or common elder, the geranium maculatum, or spotted geranium, sassafras, the wild cherry or prunus virginianus, blood-root, the Indian turnip, Beth-root, leaves of the tulip-tree, flowers of the flowering dogwood, a branch of another species of cornus, a branch of the viburnum (very common in this vicinity), and several other plants.

He noticed that the reader of the paper had made no mention of the fucus vesiculosus and fucus nodosus.

DR. JOHNSON stated that the cryptogams, fucus vesiculosus, and nodosus were very common and abundantly found in the harbor between high and low water mark. He omitted to mention them because he did not consider their value established.

In speaking of the order ranunculacea, the reader, DR. PIFFARD said, had passed over the pulsatilla nuttalliana, although he referred to its European congener. Viburnum prunifolium and viburnum opulus were useful drugs, the former as an anti-abortive, the latter as an anti-dysmenorrhœic. The paper ought to stimulate the members to examine with more care and interest the varied medicinal plants met with in their walks and rambles in the country. Much useful knowledge might be gained in this way. If country physicians would make their own preparations from the flora surrounding them, instead of relying upon the concoctions of the druggist, they would often obtain much better results from their remedies.

DR. MORROW thought the topic under discussion was one of great interest, although the subject had not attracted the attention it merited on the part of the regular profession. Much of our indigenous materia medica, he thought, had been developed by irregular physicians. In regard to the conclusions of the author that we possessed few indigenous remedies of decided power, he suggested that perhaps they had not been investigated in a sufficiently thorough manner. Twenty-five or thirty years ago probably fifty per cent. of the remedies now in active use were comparatively unknown. Some of the most valuable remedies the modern physician possesses were scarcely used years ago. If proper attention were given to the matter, a great many plants now regarded as of no therapeutical value would be found to possess active qualities. There was one objection to Dr. Piffard's recommendation in regard to the country physician preparing his own medicines, it was that medicinal plants varied much in their active therapeutical properties according to the season of the year in which they were gathered, to conditions of climate and soil, and the way in which the preparation was made. Many unreliable preparations would result if every physician were his own pharmacist. Dr. Morrow thought that the therapeutist could obtain more positive and direct action and would be more apt to arrive at specific medication by the use of vegetable remedies than by employing the inorganic.

DR. SEXTON stated that since listening to Dr. Johnson's paper and the remarks made upon it, it had occurred to him that he had in his library a journal, edited by Dr. Drake, of the Mississippi Valley, in 1827. The Society, on inspecting the book, would probably be surprised to find how much study was given to indigenous plants at that time.

Dr. Sexton also remarked that some two or three years ago his attention was drawn to the marked effect on the ear of chenopodium anthelminticum. Several cases he published in the *American Journal of Otology* for 1880. Since that time he had used wormseed quite extensively in practice, especially at the New York Eye and Ear Infirmary, where a great variety of cases suitable for treatment presented itself. The effects of the drug upon the healthy person were detailed in the paper referred to. Dr. Sexton selected several cases of acute purulent inflammation of the middle ear to whom he administered the drug in the form of a trituration. In quite a number of cases the inflammatory condition was very much diminished by the drug, and in some instances he thought that healing occurred much more rapidly than under some other forms of treatment. He had probably used it oftener in tinnitus aurium dependent upon chronic inflammation of the middle ear. In some cases he obtained good results, in others he failed. He hoped to be able at some future time to make a more complete report of collected cases; he was satisfied, however, that the drug had its decided advantages.

DR. FARNHAM thought that viburnum prunifolium possessed marked powers as an anti-abortive and as a remedy in dysmenorrhœa and menorrhagia. In

his experience drachm doses every three or four hours had certainly produced marked effects. He had had one case, a patient with hemorrhagic tendency, who had miscarried six times, and always as early as the third month. She was put upon viburnum prunifolium alone, and went on to the sixth month of pregnancy. Unfortunately, however, just at the time when the catamenial flow would have been due, she was hurried off in a carriage one stormy night to the death-bed of a relative. The excitement proved too much for her, and brought on a miscarriage, the child living twelve hours. Next year she gave birth to a twelve-pound baby. No other drug but prunifolium was used, supplemented by hygienic treatment and rest for four or five days every month, at the time the period was due. The patient had no specific taint.

Dr. Purdy had used the abstract of viburnum opulus in doses of four to ten grains with good success in dysmenorrhœa. He had not yet completed his notes. Two of his patients, sisters, had had relief for every period since the administration was begun.

Dr. Piffard objected to the statement that the eclectics had contributed much to our knowledge of the therapeutics of our plants, and gave the credit to the regular profession, and referred to Bigelow, the Bartons, Rafinesque, and others as investigators.

Dr. Johnson thought that the war of 1812 probably acted as stimulus to the study of indigenous remedies, forcing people, as it did, to look out for drugs in their own country. Shortly after the war with Great Britain, a number of great minds were engaged in investigations upon the subject of our medicinal flora. Bigelow, the Bartons, and others carried on a series of researches more thorough than any previous ones or any that have been made since. The most valuable works ever published in this country on the medical botany of the United States were published at that time by *regular physicians*. He was inclined to agree with Dr. Piffard's statement that for the knowledge of those plants whose virtues are recognized the regular profession is by no means indebted to the eclectic school.

Dr. Morrow had not intended to bring up an issue in the matter, but had simply stated his own opinion. He had in view such drugs as podophyllum, leptandra, geranium, cimicifuga, and other drugs which may be considered as representatives of our indigenous materia medica. Under irregulars he included eclectics, old Thompsonians, etc. Science was the adopter rather than the discoverer of medicinal agents.

The question, said Dr. Piffard, was whether the regular, which, in fact, antedated the irregular, was the more valuable literature in regard to the use of plants. Although the knowledge of the therapeutical activity of gelsemium was acquired accidentally, the matter was first investigated by a regular physician. For the investigation of two remedies, hamamelis and lobelia, credit is due to the eclectics. Many indigenous remedies were investigated and employed by regular physicians during the war of 1812; subsequently American drugs were considered "off color," and the abandoned medicinal agents were utilized by the eclectics.

Dr. Johnson had endeavored in his paper to go lightly over the indigenous medicinal drugs without expressing any opinion in regard to their utility, merely reflecting the general appreciation of them by the profession. Concerning viburnum he had not intended to express any views. He had been under the impression that chenopodium was a drug of foreign origin. The sea-weeds fucus vesiculosus and fucus nodosus were of economic importance, but other species, especially the chondrus crispus, were of greater value. Chondrus crispus was well known to the physician. It was employed to make jelly. It was as common from Cape Cod north as fucus vesiculosus or fucus nodosus. There was, moreover, another weed, the laminaria saccharata, related to the laminaria digitata, which was used by the people as food. He was gratified to think that he might have induced the members to pay further attention to this very interesting subject of indigenous remedy. Even in his experience as a practitioner of medicine, he had seen many therapeutical fashions. A large number of plants were investigated in the early part of the century and then cast aside. The discarding of these remedies was largely due to the influence of the eclectics. Thompson, in his ignorant but energetic way, endeavored to make people believe that mineral remedies were dangerous; he limited himself to a few powerful vegetable drugs, purged, nauseated, and sometimes killed his patient, and caused these medicinal agents to fall into disrepute. The regular profession naturally turned to mineral remedies, and the eclectics took up the vegetable drugs the former had described.

A sample of yerba santa, a plant growing in large quantities on the Californian mountains, was exhibited by Dr. Fuller. It was a remedy which had been used by the Spaniards for centuries, and was reputed to have slight stimulating powers in pulmonary disease, and healing properties when applied locally to cuts and lacerated wounds. A collection of elixirs having been exhibited, Dr. Piffard made a few remarks in regard to these preparations in general. "An elixir," he said, "is composed of four classes of ingredients: 1st, alcohol; 2d, syrup; 3d, various spices or aromatics; 4th, the medicine from which the elixir derives its name. It contains less alcohol, it is true, than the tinctures; the latter contain no sugar, have only the flavor derived from the drug itself, and, as a rule, are not very agreeable to the palate. Most elixirs, however, are purposely made pleasing in taste by enough alcohol, sugar, and aromatics; in other words, they are, to all intents, simply 'rock and rye,' with some medicinal agent. When we administer them we must remember that we are giving so much liquor, and that patients often continue to use them as a pleasing stimulant long after the necessity for their employment had ceased. They lay the foundation for tippling and inebriety. There are cases in which simple elixir may be used to good advantage in diseases of short duration, as, for instance, in intermittent fever, to disguise the taste of quinine. On the whole, however, elixirs are not a desirable class of preparation."

The Society then went into executive session.

Iodoform is soluble in the following essential oils in the various ratios given:

In Oil of Turpentine	4	per cent.

Correspondence.

THE COUNTY SOCIETIES AND THE NEW YORK CODE.

To the Editor of The Medical Record.

Sir: The Medical Society of the State of New York has been blamed, scolded, "scouted," and "jeered" to the heart's content of the courageous Stalwarts of the medical profession. They have had it all their own way these five or six months, and the eagerness of their bold onslaughts in the American Medical Association and the numerous State medical societies and the numberless county medical societies, has been something quite appalling to behold. But I fail to see the first man or society or association who has taken the trouble to inquire into or to recognize or give credit to the real motives of the New York State Society for the change of their Code—which may precede the abolition of all codes, after all. They have taken it for granted that they can make other people believe that the majority of the New York State Medical Society consists of greedy specialists, who are vulgar enough to give public expression to their hunger after consultations with quacks. They make also believe that they take it for granted that the change was made after mature premeditation of the few, and to the complete surprise of the many. *They know, however*, and you know, and the county societies of our State know, that such was not the case; and in regard to this fact, I want you to warn the county societies of *our State not to allow themselves to be propelled into undue action.* How would it do to once more direct the attention of the county medical societies to the fact that the change was made after the hearing and discussing of the report of a special committee appointed a year previously, and consisting of five of the best known men of the State (three of whom were once presidents of the State society), after prolonged discussion in a well-attended meeting, and during a session which was attended more fully than most of those which preceded it, *for the only purpose of preventing the county societies of our State from committing themselves to a positive policy.* It is a grave mistake, in my opinion, to tie the hands of the delegates, and to force them to vote one way or the other. It is undignified to compel their best men—and I hope the societies will (and you ought to urge them to) send their best men—to vote in spite of all they may hear and be convinced by, and to close their ears against everything but the instructions of their absent friends in their far-away counties. *The meeting of the State Medical Society next February is to decide* the fate of the Old Code, the New Code, and perhaps all codes, and, it appears to me, you ought to request the county medical societies *to send their delegates with but one binding instruction, viz., to* ATTEND *the meeting in February, in which the Code question will be discussed,* and, I hope, finally settled. Meanwhile, I think you will not be anxious to discuss again, for a long time to come, the matter which has proven a rich source of edifying editorials and alarmistic resolutions to high and low.

Very truly your friend, * *

[The situation is so well described in the foregoing letter, and the advice given is so eminently sound, that it is unnecessary to offer any comments. —Ed.]

HOW TO COUNT A RAPID PULSE.

To the Editor of The Medical Record.

My Dear Sir: In The Record of July 22, 1882, I notice an item referring to a statement by Professor Pribram, that "he had a case of 'vagus neurosis' in which the pulse reached three hundred beats per minute." In the context is an inference that such a pulse cannot be counted. In 1870, while experimenting upon the action of alcohol on birds, I found myself unable to count the rate of the heart's action by the usual method when the contractions were over two hundred and forty per minute (the heart's action is very distinct in birds). By the following simple method I was able to count to two hundred and eighty without difficulty: During a definite part of a minute, one-fourth usually, with a common lead pencil, dots were made upon a sheet of paper *synchronous with the heart-beats*, as heard over the cardiac region. The dots were then counted, and the number calculated for the whole minute. A pulse of *four hundred* could be taken in this way, provided each pulsation were distinct enough to be discriminated by the touch. The indistinctness of the separate pulsations of the heart alone fixes the limit to the use of this method, as the human hand is capable of making intelligently and with accuracy, at the rate of four hundred and fifty dots per minute, for thirty seconds, which rate is probably beyond not only that of the human heart, but also of the pulse of any of the lower animals available for experiment. I have had a sufficient experience with this method to know that it is of practical value, especially with children.

I have been astonished at the actual rapidity of the heart's action, in a few cases which I should have considered as beyond counting by any other method. All who have used the sphygmograph know how difficult it is to get a tracing when the heart is beating to one hundred and forty even; so that this instrument, to say nothing of the fact of its expense and inconvenience, is not nearly so well adapted to the taking of a very high pulse as even the simple finger and watch method. By the method described above, all movements, whether of the body or not, that can be seen, felt, or heard, can be counted up to four or five hundred per minute, provided they are sufficiently distinct to be discriminated. Fortunately, the appliances are always at hand, and their use so simple, and at the same time so accurate, that it need never be said that a pulse is "too rapid" for counting.

Very truly yours,

A. W. Abbott.

613 Second Avenue, S., Minneapolis, Minn.,
July 25, 1882.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from July 30, 1882, to August 5, 1882.

Munn, C. E., Capt. and Asst.-Surgeon. Granted leave of absence for one month, with permission to apply for two months' extension, when relieved by A. A. Surgeon T. H. Pleasants. S. O. 147, Dept. of the Missouri, July 28, 1882.

Shufeldt, R. W., Capt. and Asst.-Surgeon. The leave of absence granted him in S. O. 92, April 21, 1882, from A. G. O., is extended one month. S. O. 178, A. G. O., August 2, 1882.

HOPKINS, W. E., 1st Lieut. and Asst.-Surgeon. To proceed from Fort Adams, R. I., to Camp Washington, Gaithesburg, Md., and report to the Commanding Officer for duty. S. O. 132, Dept. of the East, July 31, 1882.

HOW TO DEMONSTRATE TUBERCLE BACILLI IN THE SPUTUM OF PHTHISICAL PATIENTS.—Baumgarten recommends the following method as more convenient than that employed by Koch, and as equally efficacious. A portion of the sputum is dried on a cover-glass, and then treated with potash—one or two drops of a thirty-three per cent. solution of caustic potash added to a watch-glass of distilled water. The tubercle bacilli can then be readily seen with a magnifying power of four or five hundred diameters, and a little pressure renders them still more distinct from the enclosing detritus of tissue. In order to preclude the possibility of confounding the bacilli of tubercle with those of other species, the cover-glass may be raised and placed aside until the layer of fluid on its under surface is dry, and then passed two or three times through a gas flame, and then on it may be placed a drop of an ordinary watery solution of aniline violet or any other nucleus-tinting preparation of aniline. All the putrefaction bacilli appear under the microscope as an intense blue or brown (according to the testing agent and its strength), while the tubercle bacilli remain absolutely colorless, and can be seen with the same distinctness as in the ordinary potash preparation. The whole process does not occupy more than ten minutes.

THE AMERICAN SOCIETY OF MICROSCOPISTS will hold their next meeting at Elmira, N. Y., commencing August 15th, and continuing four days. The first session will occur on Tuesday, 15th, at 2 o'clock P.M., and thereafter from 9 to 12 in the forenoon, and from 2 to 5 in the afternoon. The Elmira Microscopical Society will entertain all members of the American Society, and will tender them an excursion, which will embrace a visit to Watkins Glen, a banquet at the Glen Mountain House, and a ride on Seneca Lake.

NITROUS OXIDE.—Further experience has not changed the relative position or very much enlarged the sphere of action of nitrous oxide. That it is the safest of all anæsthetics has been established beyond a question. In one institution where such administration is subject of record, this gas has been given over 100,000 times, and not only without a death but without causing in a single instance symptoms sufficiently serious to necessitate transporting the patient home in a carriage. In the city of Philadelphia alone, it has been given over 133,000 times without a death, and without any injurious results. Death cannot be justly attributed to it in more than four cases since its introduction.—*F. C. Reeve, in Holmes' Surgery, American Edition.*

FOREIGN BODIES IN ALIMENTARY CANAL.—Dr. E. Field, of Red Bank, N. J., writes:

"CASE I.—A few weeks ago, I was called in to see a female suffering severely from hæmorrhoids, with the following history: Had just been confined (child three weeks old, but had no trouble during gestation); ten days after confinement was attacked with a severe hemorrhage from the bowels and protrusion of hæmorrhoids. This continued for ten days, two or three times daily, accompanied with pain, at which time she came under my care; had had no previous treatment.

"It was the third attack of the kind she had experienced, but the bleeding had been slight in comparison with the present one, and had been easily controlled; was always more or less constipated, going days without a passage.

"The hemorrhage continued in spite of treatment, the patient declaring she passed a quart of blood at each stool; in one she noticed some pus. The next day, in reducing the hæmorrhoids, which she was able to do easily, she felt something prick her finger, and after they were reduced felt a sharp pricking in the rectum; the following day there was pricking in the anus with the passage and upon examining the stool a pin was found bathed in pus.

"On the same day her courses came on and lasted three or four days, being the fifth week after confinement. Since that time (two weeks) the hemorrhage from the bowels has been very slight, merely a trace of blood with the passages, and the hæmorrhoids seldom protrude.

"The pin was an ordinary one, such as is used by ladies, was straight, and discolored. The patient tells me it was not expelled without some effort on her part; was pulled away with her fingers when she found the point protruding, and the pus was very tough, clinging to the pin. Nothing peculiar in any other particular about it.

"CASE II.—Was called hastily to see a child, eighteen months old, who had swallowed a thimble. The child, in playing about the floor, had placed the thimble in its mouth unnoticed by its mother. On raising her up she suddenly choked and the accident was discovered. To make matters worse, the father, upon finding that he could not remove, was advised to push it down, which he attempted to do. Upon examination I could feel the upper and smaller edge of the thimble in the fauces.

"The child was vomiting continuously. By careful manipulation, and being blessed with an unusually long finger, I succeeded in passing below the thimble, turned it in the pharynx, slipped my finger into and removed a thimble an inch long, open at both ends. To the latter condition the child probably owes its life, as she could breathe through it readily. It was in the throat about forty-five minutes.

"CASE III.—A girl, seven years old, was picking her teeth with a bent pin of ordinary size, when by some misfortune she swallowed it. Her father came to my office, saying she was suffering much pain.

Being unable to attend the case immediately, I sent a brother physician. Upon examination, he found the pin low down in the œsophagus. While attempting to remove it with forceps, it slipped from his grasp. The child was immediately relieved, and so far has suffered no ill-consequences."

Climatic Treatment of Phthisis.—In a communication to The Record, Dr. R. B. Haywood, of Raleigh, N. C., states his doubts as to the propriety of sending consumptive patients to Florida and other debilitating climates. He expresses himself as being a convert to the views of those who, adopting a tonic plan of treatment, have with benefit turned the invalid current to the seashores of New Jersey. During his thirty-eight years of practice he has never sent a patient to Florida *with any satisfactory result.* On the contrary, he is convinced that the breaking down of the tubercle is hastened by such procedure. The climate of Florida, according to our correspondent, is exceedingly debilitating, miasmatic, and productive of complicating pneumonia. The country is subject to "northeasters," the temperature varies greatly from day to day, and insect life is particularly obtrusive and harassing. Experience, he claims, has taught him that the humidity, particularly where the air is free from impurities, exercises no baneful effect. Sea air is tonic, pure, and medicinal. If there is any virtue in inhalations, he argues, the sea air breathed should also be of efficacy in view of the various ingredients of the sea water, which it carries with it—compounds of chlorine, sulphuric acid, lime, magnesia, phosphoric acid, etc. The effect of sea air is quickly manifested in elevating the tone of the system, increasing strength, and exercising a marked action in anæmia and general debility. For the last three years Dr. Haywood has been in the habit of directing his patients to go to Morehead City or to the town of Beaufort, latitude 34° 41', situated in the "bight" of Cape Lookout, N. C., and thirty miles from the hundred fathom line of the Gulf Stream. The sea breeze, we are told, is constant and delightfully tempered by the Gulf Stream. The mean annual temperature is identical with that of the city of Rome, in Italy, *i.e.*, 61°. Raleigh, almost on the same parallel, shows a mean of 57°, and Asheville, still farther west, one of 54°. Havanese invalids often suffer from the cold as late as March 10th, and "northers" frequently blow during half the winter. Two of the writer's patients who had sojourned at Morehead last summer express themselves as feeling almost entirely well, while a third was greatly benefited. After discoursing upon the facilities of this place, Dr. Haywood concludes by recommending it not only to consumptives, but also to the anæmic, uterine cases, to persons suffering from general debility, and as an abode for teething children.

Impure Vaccination and Puerperal Fever.—Dr. J. T. Deemer, of Manorville, Pa., reports two fatal cases of puerperal fever, which he believes to be due to the indirect result of impure vaccination. The facts are as follows: On Januury 26, 1882, he was called to see the five children of a neighboring family, whom he found suffering from an erysipelatous inflammation, resulting from vaccination with humanized virus. Two days after he learned of the death from septicæmia of a girl of twenty-one, who had been vaccinated from the same scab. Some six or seven other children also vaccinated therefrom passed through severe forms of blood-poisoning, and made slow recoveries. It is upon the following cases, however, that the author lays stress: First, Mrs. S. M——, aged forty-two, confined on February 1, 1882, was seen on February 4th and found to be suffering from puerperal fever. Death occurred within a week. During labor she had been attended by a midwife coming from the dead girl's house. The second case was the mother, aged thirty-three, of the children mentioned as being first vaccinated. On February 16th a normal labor set in at the end of the eighth month. The same midwife, being the only person to be had in the emergency, was called in and did her part well. But that night marked the onset of a puerperal fever, which carried off the patient the next day. Dr. Deemer thinks that this whole series of catastrophes was primarily due to the employment of impure lymph, by inoculation with which the poison of erysipelas was at the same time propagated.

Race in its Relation to Surgical Operations.—The black races and the oriental nations sustain injuries and operations best; next stand the Anglo-Saxons; and, according to M. Chauffard, the Latin race is as far behind them as they are behind the black race. The immunity of the Chinese and Japanese to mortality after operations is remarkably shown by the various reports of medical officers serving in the East. It is stated that pyæmia is a rare occurrence among the *Chinese*, and in a recent report of 138 operations for lithotomy performed on persons of all ages and occupations, from two years old to eighty, but eight deaths occurred. A similar immunity is said to be enjoyed by the *Japanese* in regard to pyæmia, septicæmia, tetanus, and erysipelas. In our own country, the *negro* has generally borne injuries and operations well, provided that he has not been exposed to the after vicissitudes of cold and dampness. This was remarkably shown in the experience of the negro brigades during the late American war. According to the observation of the writer, when these soldiers, injured in battle, were cooped up in overcrowded and overheated hospitals, they did well; when, however, removed to well-ventilated pavilion hospitals, and placed under such hygienic conditions as are most favorable to the white American soldier, they did badly, suffering severely from intercurrent pulmonic and other acute inflammations. The *Irish*, from their peculiar mental elasticity, also bear operations well, and so do the more phlegmatic *Germans*. The *American* is not so good a patient; his activity of mind renders him restless and impatient of restraint; he looks anxiously forward to the end of his convalescence, and not infrequently ventures out of doors too soon, and thus hinders his own recovery.—*J. H. Brinton, in International Encyclopœdia of Surgery.*

Alcohol at Meals.—Before quitting the subject of dining, it must be said that, after all, those who drink water with that meal probably enjoy food more than those who drink wine. They have generally better appetite and digestion, and they certainly preserve an appreciative palate longer than wine-drinkers.—*Sir Henry Thompson.*

Jacobi on Virchow.—Professor Jacobi's lecture on Virchow, lately published in The Record, has been highly complimented and widely appreciated here and abroad. It may interest the many friends of both subject and author to learn that the *Revue Scientifique*, for April, contains a careful translation of the whole article.

Original Communications.

TEN YEARS' EXPERIENCE IN THE TREATMENT OF STRICTURE OF THE URETHRA BY ELECTROLYSIS.

By ROBERT NEWMAN, M.D.,

PERMANENT MEMBER OF NEW YORK STATE MEDICAL SOCIETY, SURGEON NORTHWESTERN DISPENSARY, ETC.

PART II.

(Continued from p. 174.)

III.—HISTORY OF THE TREATMENT OF STRICTURE OF THE URETHRA BY ELECTROLYSIS, AND CASES OF OTHER PRACTITIONERS AND THEIR METHODS.—That electrolysis, in the treatment of strictures, is a success, is an established fact; but this is much reaffirmed by the record of the cases just stated, in which all the patients remained under observation from five to ten years, after having been dismissed as cured. Nevertheless, some of my medical friends, in speaking of this subject, appear to think that I am the only man in the world who practises electrolysis, and even authors of recent publications mention it with some doubt. For this reason, I will here give a short history of the electrolysis, and thereby prove that I have the honor to be in good company with predecessors, contemporaries, and followers, who all rejoice in similar good successes.

The first experiments were made by Crussel and Wertheimer, 1847. The pioneers of the method were Mallez et Tripier;[1] next comes Althaus,[2] Willebrand, Ciniselli, Scontetten, Bautisto Campos,[3] Dutrieux,[4] and Brenner.

Dr. Carl Weiss, of Buffalo, commenced electrolysis in a stricture case in April, 1868. He has his own method and instruments, with which he has continued to operate successfully. Being on a visit in Buffalo in 1878, it gave me great pleasure to witness his operation, and to find that our ideas on this subject, as our results, are alike. He has kindly furnished me with notes of a few of his cases, which will follow here. Simultaneously with me, Dr. T. F. Frank,[5] of Pittsburg, operated in 1874. He met with entire success, and continues his method frequently in an extensive practice. Only a few days ago I received a letter from him, in which he expresses his surprise that surgeons still persist to cut and dilate strictures, when electrolysis has such brilliant results.

As a contemporary, I am pleased to mention Dr. D. Prince, of Jacksonville, Ill., who operated April 9, 1873, and who deserves great credit for his contribution to the practical science in electricity.[6] His first case was a stricture of twelve years' duration, an aggravated case, which resisted all treatment. Dr. P. cured this case with electrolysis in sixteen days. I agree fully with Dr. Prince on this subject; but his brainwork, and the way to express it, is so original, that I cannot refrain from quoting *verbatim* a few lines from his report: "The *modus operandi* of the treatment seems to be the induction of the solvent action of the alkalies, and the disintegrating effects of diffused hydrogen. The perfection of treatment consists in so adjusting the size and force that no blood will be lost. From the encouragement afforded by these achievements, and those which have since been realized, this method of treating strictures of the urethra is rapidly coming into good repute."

An elegant writer and earnest espouser of our subject is Dr. John Butler,[1] of this city, who met with uniform success in his practice. His opinion of the value of electrolysis is best expressed in his own words, as follows: "The time is not far distant when electrization, skilfully and scientifically used, will be the universally acknowledged remedy for strictures of the urethra; and in the coming textbooks on surgery it will be shown to far surpass the old mechanical means for restoring the permeability of the urethral canal; and the old methods of divulsion, forcible dilatation, etc., will, by and by, hold the same relation to urethral surgery that heathen mythology does to the religion of to-day—taught in our schools only as matters of historical interest, belonging to the literature of a bygone age."

Others who use the electrolysis constantly are Dr. Neftel, of this city, and Dr. H. Mynter, of Buffalo. The late Dr. Benson, of Hoboken, also employed it. Dr. G. M. Schweig, of this city, had the kindness to write me on May 6, 1882. His experience I quote as follows: "For the last four years I have only employed electrolysis to remove submucous callosities or indurations of the urethra, and there *always* successfully. To remove callus, I introduce the negative pole to the affected spot, connect the positive by sponge electrode anywhere on the patient's cuticle; leave it *in situ* ten minutes, a few minutes more or less, with a current as strong as can conveniently be borne inside; if too strong for the outside, I simply move the positive electrode, and keep shifting it, as required. A few repetitions of this are usually needed." When this method was in its infancy, it was thought that the electrolysis had no influence on callus. As Dr. Schweig has been always successful in absorption of callosities, I know of no stricture which would not be amenable to our treatment; and the fact is, that during the last five years I have not met with a stricture, no matter how bad it was, which was impassable to the electrode bougie.

Dr. A. S. Wolf, of Plattsburg, now in Texas, and his son, getting acquainted with my method of treating strictures, adopted the method, and have since practised it with success. Dr. A. Wolf's son told me that while Contract Surgeon, U. S. A., in Texas, he had many cases of stricture among the soldiers of the army; he used no other means than electrolysis, and always cured his patients.

My friend, Dr. A. T. Douglas, of Rondout, now in New London, became an enthusiastic adherent of my method, and has used it with success in many cases since I read my paper before the Ulster County Medical Society, and operated in open meeting on an old case, which was known to most of the members present. The patient, a colored man, was troubled much, had been operated upon in various

ways, and his stricture always contracted again. He was cured with our method, and many years afterward, Dr. Smith, of Rondout, informed me that his patient has remained well, without having had a relapse. Dr. Douglas has sent me notes of some of his cases, from which I will copy one, contained in a letter dated Rondout, January 12, 1879:

Case reported by Dr. A. T. Douglas, of Rondout.—H. W——, aged about thirty-two years, contracted gonorrhœa in the latter part of 1874. He was treated with copaiba, cubebs, sandalwood oil, and injection. He came to me in September, 1876, complaining of gleety discharge and difficulty in urinating. On examination, I found a stricture about four inches from the meatus, another three-quarters of an inch from the first. A No. 8 bougie (American scale) passed with some difficulty. The patient was very timid about the use of the bougie, as the entire mucous membrane of the urethra was very sensitive, and a suggestion of the trial of electricity excited so much alarm that I contented myself with the use of the bougie whenever he would come to my office, which was not oftener than once a week. Finally, in February, 1877, he consented to the trial of the battery, as he was going West in the spring, to remain for some time. A No. 9 bougie could be passed tolerably easy. An electrode, corresponding to a No. 10½ bougie, was used with a twenty-cell galvanic battery, which had been cleaned and refilled about three weeks before. Commencing with two cells, the slide was slowly passed till the sixth cell was reached, when the electrode passed the first stricture, and in about the same time the second was passed, without any further increase of the battery. He went West in April, and up to that time he had no reappearance of gleet or difficulty in urinating. In the autumn of 1877 he returned. He then had an occasional gleety discharge, and a No. 10 bougie passed with difficulty; the obstructions being at the same points as before, he would not admit that he had suffered from a fresh attack of clap. He was still rather timid about the use of instruments, but finally, after a month, submitted to another trial of the battery. This time the same number of cells were employed, and an electrode, a trifle larger than a No. 14 bougie, was used, and in about five minutes both strictures were passed. In about two weeks the same electrode passed without difficulty, and he left for the West in March, 1878, at which time he was well.

I will close this chapter with Dr. Weiss's six cases and his letter explaining his method. It will be seen that his method differs somewhat from mine:

From Dr. H. Weiss.—Letter.

"BUFFALO, July 29, 1878.

"My method of treatment has changed very little since my operation in 1868, two years after the communication of Ciniselli. I find the indication for an operation at once, whenever I am unable to pass the constriction easily with a bougie No. 4. Should I deem it necessary in a special case to make myself previously acquainted with the length and structure of the stricture, I would use for that purpose a very thin whalebone bougie, having a good button, which seems the most suitable instrument to me.

"In the electrolytic operation, I was in the habit formerly of employing a bougie No. 11 or 12, perforated at its anterior extremity, through which a silver wire of the diameter of about $\frac{3}{32}$ of an inch, and well rounded at its point, could be made to project.

"At the present time I am using, as you are aware, a bougie size No. 5 to 7, armed with an isolated egg-shaped button—diameter of No. 11 to 12 bougie, from the centre of which an electrode of $\frac{1}{10}$ to $\frac{1}{16}$ of an inch thickness projects about $\frac{3}{16}$ of an inch, and into which the somewhat thinner induction wire passes. This instrument has the advantage, 1st, to pass and be manipulated easier; 2d, it always and only comes in contact with the constricted part, as the most prominent point, crowding away the healthy tissues of the urethra.

"I give to the induction wire and to the isolating bougie *only that curve* which is in conformity, approximately, with the curve of the urethra, up to the point of stricture, and avoid the greater one, which would be demanded by the urethra in its upper third.

"Up to the present time, I have operated upon every one of my patients in the erect posture, with the legs wide apart, standing between two chairs, upon whose backs on either side he may support himself.

"I did this to avoid every possible pressure on the sides of the urethra, and to regulate the direction of the electrode through the rectum if it should appear that the instrument was producing tension of the membranous canal toward one side.

"I have in this manner operated so harmlessly and successfully that I have contracted the habit of considering the whole manipulation as a very trifling operation."

Six cases reported by Dr. Carl Weiss, of Buffalo.

CASE I.—R. R——, restaurant keeper, robust and of a healthy constitution. Has suffered for two years with stricture of the urethra consequent on gonorrhœa. Has had no treatment before. Tried to pass bougie No. 4, but without success.

First operation, April 16, 1868.—Instrument used, bougie No. 12, with a small aperture in front, to permit a passage of a silver wire of the thickness of $\frac{1}{16}$ inches.

The bougie was passed down to the stricture, five inches from the meatus, then the silver wire was pushed on until about $\frac{2}{16}$ inches of it protruded; it was then held firmly in this position.

A Siemens galvanic zinc and copper battery of fifteen elements was used for thirteen minutes, when the stricture of the length of $\frac{1}{16}$ inch was passed, as shown on a graduated bougie.

Only at the beginning of the operation did the patient complain of slight pain, which, however, diminished in a few seconds to only a prickling sensation. Ordered rest and a bland diet. In a few hours the patient voided his urine in a strong, normal stream, to his great satisfaction, and *without pain.*

No reaction or any other bad symptom followed. A few months later, however, the patient began to notice a little diminution of the size of the stream, but only seven years later could a decided contraction be demonstrated (at the occasional introduction of the bougie by the patient himself), so that the patient himself wished a repetition of the operation, especially as he intended making a trip to Europe. At the examination, bougie No. 4 could be passed 5½ inches, but No. 5 would not pass the stricture.

Second operation, March 11, 1875.—Instrument used, bougie No. 6, with an egg-shaped button, equal to No. 11, from which the silver wire ($\frac{1}{64}$ inch thick) protruded $\frac{3}{16}$ inch, and into which the battery wire ($\frac{1}{16}$ inch thick) ended.

The action of a carbon-zinc ammonia battery of

eighteen elements allowed the bougie to pass the stricture, which proved to be $\frac{5}{16}$ inch in length, in eleven minutes. He felt the pricking of the electricity only a few seconds, without really having pain. No reaction followed. Patient voids his urine in a strong stream and without any pain. In the course of two years there was little change, but during the last six months patient observes a diminution in the size of his stream, which prompts him to pass a bougie occasionally. No. 9 can be passed, but not at all times and always with a little difficulty.

Case II.—McG——, Englishman, of robust stature, has suffered for a long time with an urethral stricture of gonorrhœal origin. The stricture is situated 4½ inches from the meatus. Bougie No. 5 is still able to pass it.

Operation, June 8, 1868.—Instruments used, bougie No. 12, with silver wire as in Case I. An application of eighteen elements of Siemen's battery for fourteen minutes permits the passage of the instrument through the stricture in its full length (¼ inch). Slight pain in beginning which ceased after a few seconds.

The patient being sceptical as to the immediate effect, he was encouraged to pass his water, which, to his great astonishment, flowed in a strong, full stream. He took his leave, promising to return next day with the means of substantially expressing his gratitude. As he did not make his appearance, however, further observations could not be made.

Case III.—Michael Z—— (of Canada), aged seventeen, comes for treatment on account of a false joint of the right arm, following an ununited fracture. His cachectic appearance gave rise to a thorough examination, which revealed that since his earliest childhood he had great difficulty in voiding urine.

A stricture was found situated 3½ inches from the meatus, through which a bougie No. 2, but not No. 3, could be passed. The patient could only be persuaded to submit to any operation by the assurance that the cure of the stricture would improve his health and facilitate the healing of his arm.

Operation, May 27, 1869.—Instrument used, same as in Case II. Eighteen of Siemen's elements allowed the bougie to pass the stricture in seven minutes, the stricture being composed of a membranous ring. The operation was painless. The stream of urine never became quite so strong as the normal size of the urethra would permit, but after two years, according to patient's brother's statement, it was rather larger than smaller. The operation had obviously the most gratifying influence upon the healing of the false joint.

Case IV.—M. C——, a soldier of the garrison at Fort Porter, introduced himself as a "landsman" from the old country, with the request to be relieved of his trouble in urinating, from which he had been a sufferer for three months, as he feared detection and transportation to the hospital. Examination revealed a stricture situated 4½ inches from the meatus, and also a sparse gonorrhœal discharge. Bougie No. 9 could not be passed.

Operation, March 21, 1871.—Instrument used, bougie No. 12, with the silver wire. Eighteen elements of Siemen's battery permitted the electrode to pass through the stricture in nine minutes. Length of stricture, ⅛ inch. The pain was pretty severe, but only for half a minute, and then disappeared almost entirely. Three or four months later the patient made his reappearance for the first time and assured me that after the operation he had not had any more trouble, and also that the discharge had ceased at once.

Case V.—Louis S——, aged twenty-nine, of a very broken-down appearance, has suffered for four years from a gonorrhœal stricture. During this time he has submitted himself to different forms of —but, as it seemed, to no rational—treatment. According to his statement, he has repeatedly been totally unable to void his urine, and has then been subjected for hours to the excruciating pains of attempts at catheterization, until at last the urine would flow after a considerable loss of blood by the urethra. Examination shows a stricture, 5½ inches from the meatus. Bougie No. 4 could not be passed.

Operation, August 3, 1873.—Instrument used, bougie No. 6, with egg-shaped button of the thickness of No. 11, with silver wire, etc., as in Case I., Operation 2d. Twenty elements of the zinc carbon ammonia battery permitted the instrument to pass through the obstruction in twenty-one minutes. Length of stricture, $\frac{1}{16}$ inch. Some pain was felt in beginning, but it soon declined to only a prickling sensation. Ordered patient rest and a restricted diet. Patient promised to report in two days, but failed to do so, as he had left for Louisville on the day following the operation.

Case VI.—S. M——; history, traumatic stricture.

Operation, June 16, 1878.—Twenty-four elements of the galvanic battery were used for twenty-eight minutes, until the stricture could be passed to the length of ⅛ inch. Eighteen elements were used by me at first, but the advance being very slow and the patient not feeling any pain, I went on to twenty-four elements, by which means the advance was more rapid, and the patient still suffered no pain. A few minutes before the end of the operation the patient began to lose courage, complaining of his constrained position, and did not believe he could much longer remain in it. It being very unpleasant to me to discontinue the operation on that account, I encouraged him to hold out a few minutes longer, which he did with fortitude, obviously because he did not see me waver in my confidence when the bougie passed the stricture. On the other side of the stricture I found no further obstacle, but did not wish to explore further than 1 to 1½ inch. In withdrawing the electrode the mouth of the stricture gave a slight obstacle to the passage of the ivory button, which had the thickness of a catheter No. 11. This seemed to prove that the end of the stricture was less extensively disintegrated than the portion nearest the meatus.

July 20th.—Mr. M—— came to my office to report that he had been feeling very well since the operation, and wished to consult me as to whether it was necessary to introduce an instrument occasionally, and if so, of what kind, as the calibre of his stream had diminished perceptibly. On making an examination, catheter No. 9 would not pass the stricture. I advised a repetition of the operation, in place of the troublesome and yet not satisfactory introduction of bougies. As the patient coincided with my opinion, the operation was repeated on the following day.

Second operation, July 21, 1878.—The buttoned instrument, which could be introduced 6½ inches, passed the stricture in four minutes with eighteen elements of Siemen's, and was withdrawn without meeting with any obstacle. Although the button had the thickness of a bougie No. 12, the patient experienced no pain and left town on the second day after the operation feeling perfectly well.

IV.—The Theory and Practice of Electrolysis—Answers to Queries and Objections.—The practical part and success of electrolysis has been fully demonstrated in the foregoing pages by clinical facts. The modus operandi can be learned from the detail related in those cases, and therefore I will not repeat it here. I also exclude all matters pertaining to strictures in general, or treatment by other means than electrolysis, as not belonging in the scope of this paper. In regard to the theory of electrolysis, the galvanic and faradic battery, physiological effects of electrolysis on mucous linings, with experiments, therapeutical action of electricity, method of application and examination of the stricture, I refer to my former paper of 1874, as I adhere still to its contents as described there. The present paper is only intended as a continuation of the former, with additional clinical facts and observations for ten years, addendas and answers to objections raised. Some of my friends have even doubted the existence of electrolysis, and that it has any influence on strictures. Now the decomposition by electrolysis is a known fact, taught in any text-book on elementary chemistry; and therefore I will not dwell on its description. But for our purpose will only add an experiment, to prove that the two currents of electricity act widely different, and that we must use the galvanic constant current for our purpose.

Experiment for the Decomposition by Electrolysis.—Two small glass bottles are nearly filled with a solution of iodide of potassium. The bottoms of these bottles are substituted by a piece of a pig's bladder. The necks of the bottles are then closed by a cork, through which runs a conductor; a small wire of platinum is best. Both bottles are then placed in a dish of water; they may be apart from each other six inches, more or less. To the platinum wire of each bottle is attached one pole of a galvanic battery, which is then started with six or more elements. Six cells will illustrate the effect of the electrolysis, but a stronger current of course gives proportionately more effect. We will now observe in the bottle connected with the positive pole that in the white solution streaks of yellow appear, and in about five minutes the bottle contains only a dark yellow fluid, which is the iodine set free. At the negative pole the bottle's contents remain white, with white bubbles of froth in it, which is the hydrogen and potassium.

If we make the same experiment with a faradic battery, no change takes place. This practical experiment proves that we can only use a galvanic battery for the electrolysis, that at the seat of the stricture we must use the negative pole, and that the effect for the cure of stricture is a chemical decomposition by absorption, which I have called "galvanic chemical absorption." The negative pole acts as a caustic alkali, which will not hurt. Weak currents will only decompose, stronger applications will show a caustic effect, and very strong power will burn like galvano-caustic. We have it in our power to select and regulate the current, and thereby choose a method applicable to the nature of the case.

Methods.—This answers many questions which I receive, like: Have you changed or modified your method? How is it that others have a different method? Do you burn through the stricture? How can a stricture be absorbed? There is everything in a method. In my former paper I have mentioned and described three forms for use. Now I have explained this more in detail, and I have no objections to methods of others who apparently differ with me but in reality use the same principle. Some may have different instruments or another form of battery, or other battery fluids: all this makes no difference so long as the indication is fulfilled. There are different kinds of strictures, which is all conceded, but that does not need so many different forms of procedure in treatment. The condition is first to find out the nature of the stricture in all its detail and relation to surroundings and to the patient himself. Then make up your mind what to do and what you want to accomplish, at the same time not to want to accomplish more than you can do reasonably. Make your plan for the operation, how to do it, select your instruments, and operate with skill. There is a method in the method, and that is the art which leads to success. To the question, if I have improved my method, I have to answer that I have improved only myself by getting more dexterous, having operated so many years in the same direction. My opinion in relation to our subject is the same now as I have related it eight years ago. *Why then have others failed, and why is the electrolysis in urethral stricture not generally adopted?* In order to have success with strictures, it is necessary to be a skilful surgeon, who understands the anatomy and is master in handling the instruments. For our purpose the operator must also be an expert in electricity besides a surgeon. Some of our young men consider themselves surgeons after buying a new set of instruments in a rosewood case. If they do an operation bunglingly, they condemn a good method: and some old men never wish to adopt any innovations because they have not learned it at college. But old men must die off, and progress can not be hemmed in.

To what kind of strictures is electrolysis applicable? I answer, to all. While I was timid formerly, and said there might possibly be strictures of small calibre, or calcareous deposit, which will not yield to electrolysis, I now pronounce that during ten years I have not found a case which was not cured by our process, no matter how small the calibre, or how firm the deposits, and I have had to treat almost all bad cases. Most of my patients came from remote places, sent by their physicians. If their cases had not been very aggravated, they would not have come from Ohio and Illinois, and they could have been cured easily at home. Hundreds of cases have been under my care of all kinds of aggravated stricture, as traumatic and with complications, and not in a single instance has a failure of this method been recorded. Some patients have only come for consultation, or after one *séance* were persuaded to try another method, others have left for the country before being cured, some have absented themselves for other reasons. Certainly, that class I cannot claim as my patients, and they are excluded from my record. What is meant is this: all patients with strictures under my care, who have attended as directed, have been cured. The record of the cases has been taken with great care and is correct. I recollect once that a medical friend suggested that the stricture so treated might have been spasmodic only, when the history of the case stated exactly that it was an old traumatic stricture, complicated with a perineal fistula, having been operated on by an eminent surgeon before, and always contracted again. Besides, a spasmodic stricture will not yield to the galvanic current; on the contrary, will be made worse. The cure for a spasmodic

stricture is the faradic current. Many times my friends have volunteered to say that the treatment of strictures by electrolysis is nothing else than a dilatation, and that the electricity is only an innocent plaything. I will be glad at any time to demonstrate the action of decomposition by electricity. Often I have shown the action in the following manner: A bougie was introduced into the urethra and arrested in the stricture. Gentlemen present in turn each tried to pass the bougie through the stricture without being able to move it. Then, without moving the bougie, it was attached to the negative pole of the battery, and without any pressure in two minutes the bougie had passed and absorbed the stricture. This experiment has been made often in the presence of eminent gentlemen in the profession, and can be found in recorded cases. Hence the electrolysis of strictures is effected by absorption by the negative pole of a galvanic current. Another objection comes from Dr. Teevan, of London,[1] who condemns the method, because I recommend an interval of four weeks between the *séances*. But the doctor does not say *why* that is an objection. I should think it is a good feature not to trouble our patient in four weeks, who is made comfortable in the first *séance*, is not detained from business at all, can earn his living, is free from all pain and inconvenience, and after four weeks comes again to the office during his leisure hours. What a contrast to other bloody and painful operations, when a patient is kept in bed and cannot attend to his business. I have mentioned several methods, and the records of cases will show that I have operated at intervals of two days when necessary or practicable. The four-weeks' interval is mentioned as a precaution, when the second method of *galvano-cautery* is practised. But let me quote from my first paper of 1874, page 13:

"*First method.*—Electrolytic action by mild currents from batteries united for tension, produces gradual chemical absorption as before described. My predilections are in favor of the first method, and I use it because it is more desirable. If circumstances permit, I operate with it in preference to all others because it is safe and never has been followed by accident or ill effect. In fact, *it is the procedure here advocated practised and illustrated by cases.*" Therefore to sum up: There is no interval of four weeks practised, recommended, or needed in any *usual* operations. Only under certain circumstances a longer interval may be desirable, according to the method employed and general principles involved. Consequently Dr. Teevan's objection is entirely unfounded.

The next question is, if electrolysis involves any danger, to which an emphatic answer is given, "No." If a clumsy operator makes a false passage, or an instrument breaks in the bladder or ruptures parts, nobody will condemn all catheters in consequence. Concomitant accidents or intercurrent diseases may happen to the injury of the patient; but the operation of electrolysis, *as recommended by me*, is perfectly safe. Urethral fever happens sometimes after a single catheterization, but I have always avoided it in electrolytic application, if I had control over the patient.

The rule for avoiding urethral fever is to handle the parts not more than the patient's condition will permit, to give an antipyretic, and to insist on the *necessary* rest. In speaking of the necessary rest, I do not wish to be understood that every patient *must* rest after an electrolytic application, but this depends on the surgeon's judgment to give the orders in each individual case according to indications. Most of my patients were not detained at all from business; some went travelling immediately after treatment, as will be seen by perusing the notes of the recorded cases. Hence our method is just as safe as any catheterization, but safer than most methods practised for the cure of strictures of the urethra.

INSTRUMENTS.—*The battery.*—Any good galvanic battery answers our purpose, if the current is steady, without giving shocks by interruptions. A large surface of battery will cauterize with more intensity than any other known caustic. By using the necessary amount of electric current thus generated, to enlarge the sphere of action, too much inflammation of the surrounding healthy tissues may supervene, and thus aggravate the disease. No action should ever destroy healthy tissue, and the concentration of the electric current should be strictly confined to the diseased locality only. The battery works to advantage in the two following points:

First.—The intensity of the current can be augmented gradually, cell by cell, without any interruption of the current, so that the patient will hardly perceive the increase of intensity.

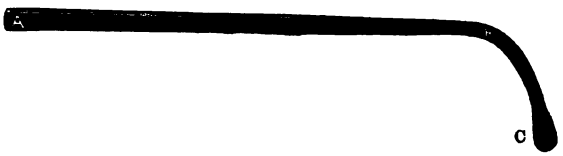
Second.—The quantity of electricity is reduced to a point sufficient to produce the most intense action on a very limited space. I generally use a carbon-zinc battery made for me by Luis Drescher; other batteries were made to order on the same principle for me by Chester. However, the make is immaterial as long as the current is steady, the slide easily moved without any interruptions of the current. The cells I have had made of hard rubber, which are preferable to glass, because they are lighter, do not break so easily, and on account of their thinner walls contain more fluid.

A rheostat, attached to the battery, is a nicety, convenient for some cases, but as a rule not needed, as the current can be sufficiently graduated from cell to cell, if the battery is well constructed. The amount of electricity to be used depends partly on the amount of work to be done, and particularly on the feeling and susceptibility of the patient, and for these reasons a galvanometer is of little use. More important is the electrode bougie, and the greatest care is needed to have these instruments perfect.* For many years I have used flexible catheters as insulators, inside of which runs a copper wire as the conductor; the end of the wire is attached to the negative pole of the battery; on the tip of the wire is a metal silver-plated bulb, which is connected with the cut end of the catheter, so that it makes a continuous smooth surface. For years I have experimented with all kinds of instruments in order to improve these electrodes. Novelties are not always improvements, and through many failures I have now come to certain conclusions, as follows:

Sounds for the correct exploration of the urethra must be either entirely flexible or stiff and unyielding. To the first class belong Nélaton's and Jaques's, and they adapt themselves to the curves and inequalities of the urethra. I have tried to use them for electrolysis; they may answer for certain cases, but, as a rule, they are not applicable for our method. The type of the second class of explorers is the steel sound. The operator has it in his hand and will to guide the sound where he pleases; it will not diverge from the course it is directed in, it is firm,

[1] London Lancet, June, 1880.

never yielding. If the sound makes a false passage the operator is responsible for it. The curve is not so material, but I prefer a short curve; because the operator can guide with his hand and adapt thereby the instrument to the curve of the urethra. Next, in a short curve, if the sound has a groove at the end on its convexity it can be used as a tunnelled sound, which is often very useful. The old-fashioned large curves were mistakes and have done much mischief in surgery. The guidance of an instrument can be done with a certainty only in a straight line; the more the opposite end diverges toward the curved line of a circle the less will it be influenced by the force at the straight end.



This is better illustrated by the diagram: If the instrument is pushed from A the influence of the force is most at B, and has not the slightest moving power at the end at C, but if the force is increased, the instrument will sooner break through an iron wall at B than move at C.

For this reason the old large curves must be condemned, as also all instruments which are elastic in whole or part, hence elastic bougies will never be certain. The model sound is the "tunnelled." By its construction Dr. Gouley has become a benefactor to suffering humanity.

The surface of our bougies must be smooth and well insulated, without any inequalities. The only points not insulated and acting as conductors are both extremities; the upper one a round wire rod for the binding post of the negative pole, and at the tip the egg-shaped bulb, which is the working power to pass through the stricture. Some consider a conical end best, and it may do for those who wish to engage the pointed end into the stricture, and then by a certain force push the thicker part of the instrument after it, which is nothing else than a forcible dilatation. For our purpose this would be objectionable, in fact would spoil the operation. For instance, if the instrument is a No. 10, and its conical end tapered equal to a No. 7, the electrolysis can naturally not work the stricture to a larger calibre than just No. 7. Now the end has passed and is free, while the thicker part of the instrument hangs, grasped by the calibre of the urethra, and cannot follow into the place nor push its extremity, or, in other words, the No. 10 cannot occupy room of the size No. 7. As the only factor of reliance in this treatment is the electric power of absorption, and not any force, it is evident that the egg-shaped bulb answers best. The length of this egg-shaped extremity is in proportion to the size of the instrument; for a No. 11 French the end is three-sixteenths of an inch, and for a No. 21 French three-eighths of an inch.

For examination of the urethra, better expressed for the condition of the stricture, the whalebone bougie à boule is an admirable explorer, and teaches *to see* with your fingers, whereas for real ocular inspection I use the endoscope as heretofore.

Conclusion.—Several hundred cases of stricture of the urethra have been treated by myself. Of perambulent patients, or those seen in hospital and dispensary service, the records are of no use, as it is impossible to follow up such cases for further reference. But from private practice I can easily tabulate one hundred cases who have been kept under observation for years, many from five to ten years, and all are well. Some of them *may* have acquired a new affliction, the calibre of some urethras may have contracted a little, or not have been restored entirely, and microscopically a pathologist n ay find a deviation from abnormal states, but for all practical purposes these patients feel well, are well, and enjoy life, without any interruptions to their daily avocations, and even do not wish any more improvement to their state of health. This article does not exhaust the subject under consideration, nor is it complete, but its intention is carried out, which is to continue my paper of 1874, with the clinical facts and observation of patients for many years. The conclusions are easily arrived at and expressed by saying in the treatment of strictures of the urethra, during ten years' practice, electrolysis has given entire satisfaction, and among hundreds of cases not one needed any other method.

New York, July, 1882.

THE RECOGNITION OF MICROCOCCI.

By ROLLIN R. GREGG, M.D.,
BUFFALO, N. Y.

The criticism by George M. Sternberg, Surgeon U. S. A., in The Medical Record of April 8th, of my paper entitled "No Bacteria in Diphtheria," which appeared in The Record of February 11th, I have read with much interest, though I was not a little amused at his remark that my statements "could hardly come from one familiar with the literature of the subject." I can hardly see how one could have the boldness to make such assertions as my paper contained without such familiarity. But this is of no consequence in discussing so great a subject as the question of the existence or non-existence of bacteria in diphtheria; so we will pass on to much more important matters.

Were it true that I am not familiar with the subject, I cannot see that Dr. Sternberg has made a single valid point against my positions. The first thing said in my previous paper, after introducing the subject, was that "there is not the slightest difference to be found recorded by the best observers between the three classified forms of so called bacteria in diphtheria, namely, spherical, rod-like, and spiral, and the three exactly corresponding forms of coagulating fibrin, namely, granular, thread-like, and spiral."

Now, this statement was either true or false. If false, and Dr. S. had the proof of it, how much easier would it have been for him, and more pertinent to the subject, to have given that proof than to have gone through a long argument, based in part upon wrong premises, as we shall see, to show that I was wrong. The proof of my error in this regard would have overturned one of the fundamental principles upon which the first half of my paper rested, and thrown much discredit upon the whole of it. If, on the contrary, that statement was true, I cannot see that I was far out of the way, or very unjust to those distinguished men he names when I said "no observer of these assumed bacteria appears ever to have stopped for a moment to consider whether his alleged bacterial forms might not be the long and well-known forms of coagulated fibrin,

which are always found existing in the same positions and under precisely the same circumstances that bacteria are said to be found in diphtheria." But let us have the proof of my error, if there is any, and I will bow most humbly to it; otherwise both of these assertions stand unrefuted.

What is wanted more than all things else in connection with this subject is a familiarity with the *facts* of nature and of disease that apply to it. Therefore, amid the throng of individual opinions, beliefs, and assumptions upon all sides of the question, which are none too often based upon known truths, let us see if we cannot get right down to solid facts, and to what is actually known upon it.

To begin with, then, I will state one of the fundamental facts in diphtheria to be that granules and fibrils of fibrin are *always* present in enormous numbers in and about every diphtheritic membrane, and may also be found in every other locality in the human organism where bacteria are said to be found. Well, such being the case, I will be greatly obliged to Dr. Sternberg if he will point out a single instance where Pasteur, Oertel, Cohn, Klebs, Bollinger, Eberth, Koch, Klein, Wood, Formad, or any of the other numerous observers of, and writers upon, bacteria, have told their readers that there are great numbers—tens of thousands—of granules and fibrils of fibrin in every such membrane of any considerable size, and in the tissues about and beneath them; which granules and fibrils are of the same general forms, sizes, color, etc., of bacteria; or where they have given warning to others that they must be careful to discriminate, if making observations for themselves, between these similar forms of entirely different things; or, finally, when and where they have told their readers *how* to discriminate between these two sets of forms which are so nearly alike, and which are inextricably mingled together by the million, if, indeed, there are bacteria at all in diphtheria, as they claim.

This strange and unaccountable oversight on the part of so many educated and scientific men, on so simple a subject, is no trifling matter. They are all, I believe, annually instructing large numbers of medical students, and assume to instruct practitioners of every age and grade who read their writtings; but they have sadly neglected a plain and most important duty, if they have not told those who look to them for correct information, of the existence and presence of the said exactly corresponding forms of fibrin mingled with their assumed bacteria, and how to distinguish the one from the other. What is thus said applies so far only to those whom the said observers and instructors assume to teach, and the giving them accurate information by which to recognize with certainty what they are looking for. But when this teaching comes to be carried into the broad field of practice, it at once becomes of infinitely greater importance, and mistakes are certain death to numerous subjects.

If bacteria exist at all in diphtheria, and are the real cause of any of the fatal conditions of the disease, the profession should not rest until it finds what will destroy them the most effectually, without harm to the patient. If, on the contrary, they do not exist, all attempts by the physician, with harsh agents, to destroy, in his patient, what is only a phantom of his own imagination, would be fraught with the greatest mischief, and cause the inevitable sacrifice of many victims who might live without such treatment. Therefore, we must know the truth on all these points as soon as possible.

In saying all this, however, I would not knowingly detract from any man's well and justly earned laurels in any department of the greatly complicated field of science, or of scientific medicine. There is little enough honor bestowed now upon such men. But these subjects are higher than any man or number of men, and must be settled in the interests of truth, which cannot be done without they are thoroughly agitated and discussed in all their bearings.

To some, no doubt, it may appear that Dr. Sternberg has already sufficiently answered most of the preceding strictures when he says, "We have other and very positive methods of distinguishing these minute vegetable organisms," than "optical appearances alone;" and upon one of these he appears, himself, to place more reliance than upon any other, if not more than upon all others combined, for settling the questions at issue. He states the point as follows:

"Micrococci are unicellular vegetable organisms which, in a suitable medium and under favorable circumstances, multiply rapidly by fission, and the most reliable test is conceded by all authorities to be that of cultivation in a sterilized liquid. Minute spherical bodies, which multiply by fission, and which in the process of multiplication are joined in pairs or chaplets, are living organisms, and not granules of fibrin."

But is Dr. S. quite certain that all this is reliable, and a test from which there can be no appeal, when applied to those abnormal forms (bacteria as he calls them; granules of fibrin as I say) that are developed in connection with diphtheria? Let us see. Things are not always what they seem, and it is just possible than an element of error has crept in here with reference to diphtheria, that must be eliminated before we can know scientifically all there is of the subject. It should be understood at the outset, however, that no question is here raised with reference to the distinguishing features and method of development of real micrococci in the vegetable world where they properly belong. It is only in regard to their existence and development within the living human body in disease that this discussion is carried on upon my part.

The quotation from Dr. S. involves two points, namely, the natural development and rapid increase of micrococci by fission, wherever they may find the proper conditions of growth; and their artificial cultivation in a "sterilized liquid." To the first of these, or their increase by fission, we will first give attention. The fact is undoubtedly as the doctor states it to be in the vegetable world (no question being here raised upon that claim as already said), but did he never consider and apply the following facts bearing upon this point to diphtheria?

It is a law, or at least an invariable rule, of all organic nature, when undergoing natural disintegration, to break up in the exact inverse order of its primary growth, organs into sections, sections into fibrils, fibrils into granules, granules into their particles, and these into the elements of which they are composed.

Such being the case, the next point for our consideration is as follows: The false membranes of diphtheria are, as we know, constituted of fibrin, and this being so, they are built up by its being extravasated in a state of solution, then coagulated first into granules, when these granules unite themselves to each other "in pairs and chaplets" to form the fibrils, which next interlace to form the membrane. There is no other way by which the

extravasated fibrin, poured out from the blood as it is in a fluid condition, does or can organize into a membrane. Therefore, applying the law of disintegration of organic structures as just given to a rapidly rotting diphtheritic membrane, which is commonly seen in malignant cases, what do we find in the direction of our inquiries? The membrane rapidly disorganizes in the inverse order of its organization, first into fibrils, which fibrils next show evidence of parting at their granular unions, become constricted at those points, thus giving the appearance of chaplets, or the bead-like construction of which we hear so much, which next separate in the further process of dissolution into segments and pairs, and these into single granules. In no other way can a rotting fibrinous membrane go to pieces.

Therefore, here we have the whole question and claim of the existence of bacteria in diphtheria and the multiplication of micrococci by fission, in a rotting diphtheritic membrane, laid bare. And because the fibrils of fibrin do become constricted at their granular unions, as the first step toward their parting at those points, thus giving something of the appearance of a string of beads, then break into segments and pairs, and these into single granules, by fission, as stated, and all in more or less exact imitation of the method of multiplication of actual micrococci in the vegetable world, we have the process elevated into the most positive scientific proof that said chaplets and granules of fibrin are bacteria.

Has Dr. Sternberg never thought of these facts, or will he please tell me where the distinguished men he names have ever called attention to them, to show that here was a certain and positive source of error that vitiated all their teachings upon the subject? His great familiarity with the literature of bacteria must enable him to at once place his hands upon such utterances, if they have ever been made. But if this great fact never has been pointed out by them, what shall we say of their so-called science of bacteria; erected, as it would then appear, upon an entire misconception and wrong interpretation of a very simple question in pathology? If we are to have a "diffusion of scientific knowledge" we must first be sure that it is scientific, and that all the points are in.

Of that "most reliable test," as "conceded by all authorities," namely, the "cultivation" of micrococci "in a sterilized liquid," there is also something to be said. Here, too, we find the source of a great error, if I mistake not, when applied to diphtheria, and all for the want of proper discrimination at the outset. The sterilized liquid is broth made from the meat of a healthy animal, and heated to the boiling-point or beyond, to destroy the germs of vegetable cells that may have found admission into it. This broth holds in solution more or less of the fibrin that was contained in the juices and blood remaining in the meat after dressed for cooking. And it is this fibrin in the broth, coagulated into granules by the process called "cultivation," and it is these granules of fibrin thus coagulated, that are held up to us as the most reliable test to prove the existence of micrococci, or bacteria, in the blood and in the exudations of diphtheria.

If such are the facts, how is the coagulation of the fibrin in the broth brought about under cultivation? One of the processes is to place a small piece of diphtheritic membrane (which it must be remembered is for the most part fibrin) in the broth, and await developments. The fibrin thus introduced, whether it be in a patch of the membrane, in shreds, or only granules of it, causes that in the broth to coagulate or granulate. Consider the following proof of this fact:

Everything in nature begets its kind. This is an axiom that none will deny. So constant and universal, indeed, is it, that with many things which cannot beget their kind, properly speaking, nevertheless *induce* their kind. The least particle of the coagulum of sour milk, for instance, added to fresh sweet milk, begins at once the work that soon leads to the coagulation of that. The particle of the coagulum introduced does not in and of itself grow, or multiply indefinitely, but simply induces the change in the corresponding element, caseine, of the fresh milk that originally led to its own coagulation.

In a similar manner, particles of fibrin put into a fluid like the broth, which holds other fibrin in solution in it, induces a coagulation of the fibrin in that broth into granules. The added particles of fibrin do not grow or multiply of themselves in such enormous numbers as claimed for bacteria, nor at all. They simply induce the like change (coagulation) they had themselves previously undergone in their like substance, the fibrin of the broth to which they are added.

That such are the *facts* in regard to coagulated particles of fibrin inducing other fibrin held in solution in any fluid to also coagulate is shown by the following from "Carpenter's Physiology," page 60, where, in speaking upon the fibrillation of fibrin, he says:

"This *fibrillation* seems to bear a certain analogy to crystallization, being the result of forces which tend to withdraw the solid particles from their state of solution in the liquid, and to bring them together in a certain definite mode of aggregation; and there are certain peculiarities in the process which to some extent bear out this analogy. Thus, just as crystals will form around a nucleus of the same kind, from a solution which *would not otherwise have deposited them*, so will a fibrinous coagulum often separate from a serous fluid and form around a piece of washed clot of blood, or of the buffy coat, or of muscle or some other animal tissue placed in it, although the fluid (such as that of hydrocele) *would not have otherwise shown any disposition to coagulate.*" (The italics are my own, to show more distinctly the facts in this respect as they stand.)

The remarkable persistency in the coagulating power of fibrin, whenever and so long as any of it remains in solution in any fluid, may be seen from the following from "Virchow's Cellular Pathology," page 192:

"In many forms of pleurisy the exudation long remains fluid, and a number of years ago, a peculiar case came under my notice, in which, on puncturing the thorax, a liquid was evacuated which was perfectly clear and fluid, but in a short time after its evacuation had its whole mass pervaded by a coagulum, as is often the case with fluids from the abdominal cavity. After I had removed this coagulum from the liquid by stirring it, in order to convince myself of its identity with ordinary fibrin, the next day a fresh coagulum displayed itself, and this took place also on the following days. This coagulative power lasted fourteen days, although the operation had been performed in the midst of the heat of summer."

All this shows sufficiently the fact of fibrin coagulating, or being induced to coagulate, from any fluid in which it is held in solution; and there can be no doubt that in all similar instances to those

given by these authors, if the microscope were used, innumerable numbers of granules of fibrin, exactly resembling micrococci, would be seen in every such fluid after all the fibrin in it that could be coagulated in mass, or in shreds, were removed, while the broth spoken of would be generally, if not always, like such dropsical fluid after one or more coagula had formed in and been taken from it; that is, it would hold some fibrin in solution, but too little to allow of it being any more than coagulated into granules, or pairs and chaplets of the latter, with, perhaps, some fibrils more firmly organized, but not enough of these to form into a clot.

Another process, or the next step in "cultivating micrococci," is frequently to take a little of the broth, often no more than a drop, that has been "cultivated" with the diphtheritic membrane, and add that drop to fresh broth with the same result. And why? Simply because the granules of fibrin in that drop induce the fibrin of the fresh broth to granulate the same as though the fibrinous membrane were used. The smallest amount of the coagulum of sour milk, remember, at once starts coagulation in fresh sweet milk, in however great a quantity, and it is the same with the smallest particles of coagulated fibrin exciting other fibrin in solution to coagulate. Sometimes a drop of the blood of a diseased animal, containing the so-called micrococci, is used to start the cultivation in the broth, but as these micrococci in the diseased animal's blood are simply particles of the fibrin of its blood, coagulated therein by the disease, they induce the coagulation of the fibrin in the broth, as in the other instances.

This brings us to a consideration of the question of *inoculating* healthy animals and thereby causing the development of the assumed bacteria in them. Sometimes this is accomplished by placing a small piece of diphtheritic membrane under the skin of a healthy animal. When this is done we know that organized fibrin is placed there, and we know just as certainly that when inflammation is excited by it, the fibrin in the previously healthy animal's blood begins to coagulate locally, at first all through the inflamed part, into granules and fibrils as before shown, which are so like micrococci and rod-like bacteria that no distinctions have ever as yet been pointed out between them. This much we know. Then why are not the alleged micrococci developed in the broth, by placing the like diphtheritic membrane in it, the same? All analogy and all real facts yet known say they are.

Another process of inoculating healthy animals is to use a minute drop of blood from a diseased animal, as is done in cultivating the broth with such blood; and still another is to take a drop of the cultivated broth for the purpose. And in both of these cases local inflammation is excited at the point where the virus is introduced, just the same as though the diphtheritic membrane were used; and the fibrin in the fluids of the part is granulated in the same manner.

It must be borne in mind in this connection that proof was given in my first paper, which cannot be gainsaid, to show that fibrin does coagulate into granules and fibrils just as claimed, in every instance and in every locality where inflammation is excited. Therefore, it must do the same in every instance where inflammation is excited by inoculation with diphtheritic virus, in whatever form this is used; so this matter is placed beyond dispute, and the fact must be allowed in all discussions of the subject.

Then, when we place alongside of that fact the positive teachings of the bacterists, that the micrococci begin their local development and rapid multiplication at the point where they first secured their entrance into the tissues and blood, whether by inoculation or otherwise, and thence spread rapidly to other parts, we see that the correspondence and similarities are complete. The point where the fibrin begins to granulate rapidly under the effects of inoculation is the precise point where the alleged bacteria are claimed to begin their rapid multiplication in numbers; and the two being utterly indistinguishable in "optical appearances," so far as any differences yet pointed out, will the bacterists *please* tell us which is which?

The power of diseased or dead animal matter to compel the coagulation of fibrin, even in the living body, may be seen by the following from Carpenter, page 197:

"Again, the contact of dead animal matter with the blood appears to promote the coagulation of its fibrin in a very remarkable degree, occasioning *coagula to form* while it is *yet actively moving* in the *vessels of the living body*. Thus, M. Dupuy found that the injection of cerebral[1] substance into the veins of an animal occasioned its death almost as instantaneously as if prussic acid had been administered; the circulation being rapidly brought to a stand by the formation of voluminous clots in the heart and large vessels. These experiments were repeated and confirmed by M. de Blainville. The same effect is produced with *still more potency* when the substance injected is rather *undergoing degradation* than actually dead." (The italics here also are my own.)

If, then, a little healthy brain substance injected into the veins will kill as quickly as a dose of prussic acid, by forming "voluminous clots" of fibrin in the blood; and if any animal matter, "undergoing degradation," though not yet dead, is still more powerful in this respect, we can better see and understand the power which the vitiated broth or the blood of a diseased animal (that already contains coagulating fibrin) must have in coagulating the fibrin in the blood of a healthy animal inoculated with it.

The foregoing would seem to be sufficient to settle the questions of the cultivation of the assumed micrococci in animal broth, and reproducing them within the animal system by inoculation with diphtheritic blood or membrane; but another, though minor, point remains to be explained in this connection. That is the question of "fission," as it applies to the forms developed in the "cultivated" broth, or in the system by inoculation. But fission here is so in appearance only. The semblance of cleavage is really an act of union, not parting, of the granules; under these circumstances, therefore, exactly the inverse of what occurs in a rotting diphtheritic membrane, as will be seen by the following:

When two or more granules of fibrin first come together, and before they establish their more perfect coalescence into a fibril, there would necessarily be a line of demarcation between them at their points of juncture, which would, and no doubt has, furnished to microscopists a *deceptive* appearance of cleavage, or fission, and from which has been drawn the erroneous deduction that they must be, from that fact, micrococci; whereas such appearances in this case are the steps that these granules *must*

[1] There is no reason to suppose that cerebral substance possesses a more special influence than would be exerted by any other tissue which could be as easily mixed up with the circulating current (Note by Carpenter).

take to reach and perfect their combination into fibrils, and then into a membrane.

On the contrary, when the fibrin of the diphtheritic membrane is undergoing disintegration, it presents the real appearances of fission and multiplication of granules, as already sufficiently shown. But upon these two facts, namely, the primary union and the ultimate disunion of these fibrinous granules, which have been correctly observed but wrongly interpreted, has been erected the most remarkable and the greatest pathological error of modern times.

The bacterists have completely jumped all the formative stages in the organization of fibrin, its coagulation from the fluid state into granules, the union of the granules into fibrils, and the interweaving of these into the membrane, as though the latter could come into existence without any preliminary steps. They have considered the membrane only in its *completed* state, and a little something of its disintegration, and have used the *necessary* steps that had to be taken for it to get up into that state and down out of it as so much positive proof of the presence therein of bodies from a different kingdom of nature; thereby leaving out of their calculations three-fourths of the whole problem upon which its correct solution must rest. What kind of science is this?

Dr. Sternberg speaks quite confidently of chemical tests affording positive proof upon some points. But is he sure of this? Oertel says that bacteria "comprises forms of such exceeding minuteness" that "they stand upon the very borders of the visible," and "that as yet we possess only the most unsatisfactory knowledge of their nature and organization." How is it possible, therefore, as yet, to know much of the chemistry of such excessively minute bodies, when there is no actual knowledge of their nature, chemical or otherwise? Besides, unless I am greatly mistaken, Dr. S. will find granules of fibrin resisting destruction under many circumstances far more powerfully than it is possible for any pulpy vegetable cell or other vegetable structures excepting woody fibre. Again, what do we know, or what can we know at present, of the chemical nature of the many morbid secretions in and about the exudations of malignant cases of diphtheria, which must vitiate all chemical tests until those secretions are carefully separated from each other and thus tested; or how to compare the effects of various reagents upon any one portion of such exudations, in the presence of the others, to thereby lay the basis of accurate chemical knowledge?

I have wanted very much to go into a thorough discussion in this paper of the effects of diphtheria upon the red blood-corpuscles, their decolorization thereby under different processes, the nature and demeanor of leucocytes in the disease, the granules of broken blood-corpuscles therein, and the errors that have crept into the subject in connection therewith; but must defer all this to another time and paper. Perhaps, too, it will be just as well that this should be so, and settle one point at a time.

Recognition of American Medical Work.—It is worthy of note that one German medical journal, the *Deutsche Medizinal Zeitung*, gives a prompt recognition of American medical work. In its weekly "Runschau" are frequent quotations from medical journals in this country. Such catholicity is somewhat novel in Germany; still more so in France.

RAISING BABIES BY HAND; OR, ARTIFICIAL FEEDING OF INFANTS.[1]

By H. Z. GILL, A.M., M.D.,

PHYSICIAN TO SOUTHERN ILLINOIS PENITENTIARY, CHESTER, ILL.

The subject of the proper nourishment for infants is beginning to attract the attention which its immense importance merits. In 1881, at Salzburg, at a meeting of German physicians and naturalists, a report was made by a committee which had been appointed some months previously on the subject of substitutes for woman's milk in the feeding of infants. Some points which were well settled in the minds of most medical men of experience were here reaffirmed, namely:

First.—"That the mother's milk (woman's milk) is the only true material that is quantitatively and qualitatively suited to the development of the child, and which preserves the physiological functions of the organs of digestion, and, under favorable circumstances of growth, unfolds the whole organism in its completeness.

Second.—"That cow's milk is the only substitute for woman's milk.

Third.—"That the various artificial preparations of *crême conserve*, condensed milk, and the hundred other preparations, can in no way be substituted for mother's milk, and as exclusive food during the first year are to be entirely and completely rejected" (*American Journal of Obstetrics*, April, 1882).

Therefore the subject resolves itself mainly into this, viz.:

First.—The substitution of cow's milk for woman's milk; and

Second.—The preparation of cow's milk in order to make it a suitable substitute.

A comparison of the two is shown in the following by I. Straus ("Nouveau Dict. de Med. et de Chirurgie Practiques," tome xx., Art. Lait):

Elements.	Woman's milk. Per cent.	Cow's milk. Per cent.
Butter	2.05	3.05
Sugar of milk	4.06	5.02
Casein	2.88	4.86
Chloride of potassium	.07	.13
Phosphate of lime	.25	.18
The proportion of cream to butter is about 37 per cent.; hence the per cent. of cream in milk will be	6.75	9.45
One-fifth of the butter is buttermilk	1.35	1.89
	5.40	7.56

Donné says that woman's milk of good quality produces cream as follows:

	Volumetric test. Per cent. cream.
Woman's milk	3
Cow's milk	10 to 15
Ass' milk	1 " 2

Variation in cow's milk (*American Journal of Obstetrics*, April, 1882):

	Per cent.	Per cent.
Water	between 86.271	and 90.581
Solid matters	" 9.419	" 13.729
Of which—		
Casein and albumen	" 1.680	" 7.092
Fat	" 0.666	" 5.390
Milk-sugar	" 2.522	" 6 610
Salts	" 0.055	" 0.338

[1] Reported to the Southern Illinois Medical Association at Carbondale, Ill., May 18, 1882.

With the above capital points are included the secondary questions of breed of cattle, their care, the procuring, preserving, and preparing the milk, and such others as are studied at the various milk-cure establishments now in existence in Europe. Every practitioner has no doubt had occasion to notice the various preparations suggested and recommended in medical journals and text-books, as substitutes for the mother's milk, when this latter fails, from whatever cause; and it has appeared equally clear that the vast majority of these contained an amount of starch utterly incompatible with the digestive powers of the infant.

The special demands of my own family, as well as the general demands of my patients, led me years ago to study this subject somewhat thoroughly, so far as the literature was concerned, and to prove by my own experience the very unsatisfactory state of the subject of substitutes for *woman's milk*. I here use the expression woman's milk advisedly, for the best substitute for the mother's milk, when a substitute becomes necessary, has always been considered the milk of a wet-nurse.

We have learned that for the first two or three months of infantile life, the digestion of starch did not take place, or at least to a very slight extent, and yet the starchy preparations, or mixtures containing them, were still the only substitutes offered as food. The farthest point I had reached toward solving the problem with satisfaction until two or three years since, was the dilution of cow's milk (I always mean when a wet-nurse could not be obtained or afforded) with barley-water or barley-gruel, or oat-meal used in the same way as the barley, in the following form (see Dr. A. Jacobi: "Infant Diet;" "Rules for the Management of Infants during the Hot Season," recommended by the Jersey County, Ill., Medical Society; also, *Christian Advocate*, April, 1882). The table I had adopted, substituting the barley-gruel for the water in diluting the cow's milk, was the following, which answered very well in a majority of cases, and especially so after the child was four or five months old.

TABLE OF QUANTITIES FOR TWENTY-FOUR HOURS.

AGE OF CHILD.	Milk. Gills.	Water. Gills.	Food. Making Gills.
2 to 10 days old	1½	3½	4½
10 to 20 " "	1⅔	4⅓	6
20 to 30 " "	2⅓	6	8⅓
1 to 1½ months old	3	6¾	9¾
1½ to 2 " "	3⅓	7	10⅓
2 to 2½ " "	4	7½	11½
2½ to 3 " "	4⅓	7⅓	12
3 to 3½ " "	5	7½	12½
3½ to 4 " "	5⅓	7⅓	13
4 to 4½ " "	6	7½	13½
4½ to 5 " "	6⅓	7⅓	14
5 to 6 " "	7	7	14
6 to 7 " "	7½	6⅓	14
7 to 8 " "	8	6	14
8 to 9 " "	8⅓	6	14⅓
9 to 10 " "	8⅓	6	14⅓
10 to 11 " "	8¾	6	14¾
11 to 12 " "	9	5⅓	14⅓
12 to 15 " "	9⅓	5⅓	14¾
15 to 18 " "	9⅓	5	14⅓

It will be well to have a cup holding a gill when full; eight ordinary tablespoonfuls equal one gill. Have a bottle of the right size for each meal, either to use or as a measure.

I found, however, that in many cases, with all the care I could command, these preparations, especially in hot weather, would not answer. Recognizing, as all have, the indigestible character of the curds of casein in the cow's milk, the great desideratum was to get rid of the casein or to render it digestible. I gradually reached the following plan, as given very well in a letter from Mrs. General Martin, written in answer to a request of mine, for her to state in her own language the method by which she carried out my directions in the management of her grandchild last summer, asking of her every particular, whether varying in any respect from my directions or not:

"SALEM, ILL., March 13, 1882.

"DR. GILL: It is with pleasure that I give you my experience in the use of your invaluable recipe for the pepsinized milk. When we commenced feeding baby, we milked two cows; one was fresh, but the milk was mixed. I put ten grains (10 grs.) of pepsin to one pint of milk, beating in thoroughly, then cover and set it on a quite warm stove, there to stand undisturbed by stirring until curded, sometimes as much as thirty minutes. When solid, beat up with a spoon, strain through a coffee-sieve, if large enough to hold the curd, or a thin, strong bag, add half as much water as there is whey; sweeten to the taste of mother's milk. I found it best not to use cream. . . . I feel that many weary mothers will be grateful, and unnumbered little ones made healthy and happy . . . Our little boy is as bright and healthy a little fellow as one would wish to see. He is now seven months old, and for the past week has been taken his milk fresh with a little water and sugar in it, and he seems to be doing nicely.

"Signed, MRS. MARTIN."

[All complimentary personal remarks have been omitted as having nothing to do with the subject-matter of the letter for public benefit.] They very soon found themselves compelled to return to the prepared milk as before. I had recommended to add a teaspoonful of sweet cream to each feeding, in case the child did not seem to be well nourished without it. The prepared milk seemed to do better without the added cream. I may remark that a larger amount of the soft curd may be worked through the sieve, provided it is found to digest well; if it does not digest well (as may be known by lumps of curd passing by the bowels, undigested), let most of it remain behind in the sieve or in the cloth. The difficulty does not arise so much from a difference in the quantity of casein as from the difference in quality. This fact has been pointed out by nearly all experimenters (see Sanderson: "Handbook for the Physiological Laboratory," vol. i., pp. 527–528).

The matter of using only one cow's milk is not of so much importance as is generally supposed.

In making my experiments, I sent to E. Schaffer, of Louisville, Ky., for a fresh sample of his saccharated pepsin, which I found to act well. One ounce, costing fifty or sixty cents, will make, at least, forty packages, each sufficient for one time of preparing. A sample package of ten grains can be weighed out by the druggist, which will be about as much as will lie on a nickel, possibly a little more. A short experience will teach any one how much to use; a little more or less will do no harm, provided it be enough.

Once in a while, from some cause, the milk will not curd as usual; then a little more pepsin must be added, and a longer time will be required.

The above table is a very fair guide as to quantity at the given ages, using the pepsinized milk in similar quantities, and dilute the same with water, or possibly a little less water if the curd is pretty well taken out. If the digestion is well performed, and yet the child does not thrive, an inquiry should be made concerning the quality of the milk. It need not come from one cow; but it should have a specific gravity of from 1,029 to 1,033, and should have from six to eight per cent. (volume, not weight) of cream.

A physician may be asked to take the specific gravity; but any one can ascertain the amount of cream. A glass tube (one of the long, slender lamp chimneys, about an inch in diameter) will answer. Cork up the end where the tube is of uniform diameter, and on the outside of the tube, from a point opposite the upper surface of the cork, measure four inches, and paste on a strip of writing-paper four inches in length, divided into inches, the upper inch again divided into twenty-five equal divisions. Fill the tube to the upper end of the strip of paper; set it aside carefully for twenty-four hours. Counting from the top downward, beginning with the second line, every line indicates one per cent. of cream, and is sufficiently accurate for ordinary purposes; at the same time it is a very excellent domestic test for the richness of milk. If the specific gravity is less than 1,029, the milk is either watery originally or has been watered; if the cream is less than six per cent., it is either poor originally in cream or has been partly skimmed. The above plan of treatment in many cases has given great satisfaction, being simple and within the reach of almost any one. In large cities mixed milk must generally be taken, but it should at least reach the above standard, especially in reference to the amount of cream. This method disposes of the indigestible part of the casein by retaining it in the strainer or sieve. I have in some cases added a *compound salt* to the milk, as recommended in the Prize Essay on "Artificial Feeding of Infants," by Dr. Oliver C. Wiggins, of Providence, R. I., awarded by the Trustees of the Fisk Fund, and published by the Rhode Island State Board of Health for 1879. It has, however, not answered well in my hands, though prepared with much care. In this whole matter simplicity is one of the great points toward success.

Heroic Treatment of a Snake-Bite.—The following item is going the rounds of the newspapers. The question arises whether the swelling of the arm was the result of the snake-bite or of the gunpowder treatment: "· · · Joe Ludlum, the idiot confined in the County Manual Labor Poor House, was bitten by a rattlesnake on the forefinger of the left hand, the fangs penetrating both sides of the finger. About three minutes after the bite was inflicted, Mrs. Symington, wife of the Superintendent, split the finger on both sides with a razor, poured a small quantity of gunpowder into the wound and set fire to it. She then applied ammonia, and also gave ammonia and whiskey inwardly to the man until he became drunk. This was a very brave act for the lady to do and it saved the poor man's life. On Sunday the hand and arm were swollen three times the natural size, but yesterday the swelling had gone down, and Ludlum is now all right again."

PRACTICAL EXAMINATION OF THE URINE FOR ALBUMEN AND SUGAR.[1]

By J. H. LINSLEY, M.D.,
BURLINGTON, VT.

The importance of urinary analysis in forming a correct diagnosis of disease is now so well understood and so universally conceded by the profession that not a word need be said upon this point.

To discuss fully and in detail the entire subject of the analysis of urine would far exceed the proper limits of such a paper as this, and I have therefore confined myself to that branch of the subject which is of most practical importance and interest, to wit: the "*practical examination of the urine for albumen and sugar.*"

The etiology of albuminuria and glycosuria I shall not discuss, but confine myself to the tests for albumen and sugar, and the reasons for preference of certain reactions over others.

ALBUMEN.

Albumen, when found in the urine, is either serum-albumen, paraglobulin, or both.

Urine containing albumen has, as you all know, generally a low specific gravity, though there are many exceptions to the rule, and every specimen of urine under examination should be tested for albumen *without regard* to the specific gravity, as a urine, *besides* containing albumen, *may* be abundant in sugar.

Heat test.—A small quantity of urine is heated in a test-tube. It should be clear before testing; if not, it should be filtered. The urine may be cloudy from the presence of amorphous urates, which disappear quickly upon the application of heat. If neutral or alkaline, it should be rendered feebly acid by the addition of two or three drops only of acetic acid, as in the presence of a free alkali an alkali-albuminate is formed, which is not precipitated by boiling. On the other hand, if nitric acid (or any of the strong mineral acids) are used, an *acid-albuminate* will be formed, which, in turn, is also not precipitable upon the application of heat.

Acetic acid, if in excess, may cause a cloudiness from the coagulation of dissolved mucus (mucine). If, after observing the above precautions, we have a faint cloudiness, or more dense opaqueness upon heating, we are positive of the presence of either albumen or the earthy phosphates. To distinguish between these two, we add a drop of nitric acid. If the precipitate clear up, the earthy phosphates form the cloudiness; if permanent, we have albumen present. The statement, found in some works on this subject, that the earthy phosphates are only precipitated when the reaction is neutral or alkaline, cannot be relied upon, as they will often form a precipitate upon heating when the reaction is feebly acid. By the test just mentioned we may form an approximate estimate of the amount of albumen in the following manner (Hofmann and Ultzmann): Fill a test-tube one-third full of clear, filtered urine, and heat, having the reaction feebly acid. A slight turbidity after heating, the urine still being transparent, with only a feeble opalescence, indicates a small amount of albumen, and only after long standing a light flocculent sediment forms. If the urine becomes cloudy by heating, and the albumen separates out as flakes, and a layer

[1] Read before the semi-annual meeting of the Vermont State Medical Society, June 7, 1882.

comes down on the bottom the thickness of a finger, then albumen is present in moderate amount. If albumen be precipitated in large lumps, and not, as in the other cases, near the surface of the fluid, but lower down, where the flame surrounds the test-tube, and appears to be of a creamy consistency, then albumen is present in great amount.

To compare the amount of albumen one day with another, we must boil a like quantity of urine in similar test-tubes, and compare the mass of the sediment after it has well settled.

In case there is some doubt as to the presence of a slight cloudiness in the sample of the urine boiled, it should be compared with an equal quantity of the same urine in a similar test-tube which has *not* been boiled, when the cloudiness, if present, is easily discernible.

Heller's, or the nitric acid test.—A test-tube is filled about one-half inch deep with C. P. nitric acid. Upon this about an equal amount of urine is allowed to float, the test-tube being held at an acute angle. (The urine can best be introduced by means of a pipette.) A white ring is formed at the junction of the two fluids by either of the three following substances: 1. Albumen; 2. Urates; 3. A resinous substance found in the urine after the ingestion of spirits of turpentine or balsam copaiva. To distinguish between the ring formed by the urates and that by albumen, we heat the mixture slightly, care being taken to hold the test-tube as quiet as possible. If due to the urates, the ring promptly disappears with little heat. Albumen is not changed. To distinguish between the resinous substance and albumen, we add a few drops of alcohol, when, if due to the above substance, the ring is immediately dissolved, while the albumen may be further precipitated.

The ring of albumen in all cases is sharply defined, and is not dissipated by the above means, while the ring formed by the urates is irregular, is formed higher up than the albumen ring, and shades off gradually into the urine above.

The two tests just given are *the* reliable ones. If the practitioner, after carefully applying them, fails to detect albumen, he may rest assured of its absence in the specimen under examination.

Often times a dark garnet-colored ring is formed at the junction of the nitric acid with the urine, which is not to be confounded with the ring formed by the substances just mentioned. It is due to a decomposition of some of the coloring matters by the acid.

In the test above given, if the zone is faint and feebly white, and has no lumpy appearance, but is nearly transparent, and only visible as a sharply defined line on a black background, it is safe to say albumen is only present in small amount (less than one-half per cent.), generally one-tenth per cent.

If snow white, opaque, and distinctly recognizable without the black background, and of a flocculent appearance, it is present in quantities varying from one-fourth to one-half per cent. But if it appear lumpy and flaky, and falls more or less to the bottom, and upon stirring with a glass rod becomes of a creamy consistency, then albumen is present in large amount; from one to two per cent.

Alcohol test.—By some observers the alcohol test is recommended, which consists of adding to a small quantity of urine, in a test-tube, about one-fourth its volume of alcohol (95 per cent.). If albumen be present we have a coagulation of the same. The objections to this test are, that besides albumen, alcohol precipitates oxalate of lime, probably the ammonio-magnesian phosphate, and a granular amorphous matter whose composition is unknown (Piffard).

Hofmann and Ultzmann.—Acidify strongly with acetic acid and add to the urine its volume of a cold saturated sodium sulphate solution, and boil. If albumen be present we have a white precipitate.

Neubauer and Vogel.—If a solution of albumen be treated with acetic acid until it has a strong acid reaction, and then a few drops of ferrocyanide of potassium solution added, a white flocculent precipitate is produced.

Carbolic acid test (Whittaker).—If a drop or two of strong carbolic acid be shaken up with the urine in a test-tube, if albumen be present the urine will turn milky. Precaution should be observed that too much acid is not added, as you are all familiar with the whitish appearance of a mixture of carbolic acid and water, if of sufficient strength.

Picric acid test (Gallipe).—Drop into a perfectly clear urine a cold saturated picric acid solution. If a white cloud form, then is albumen present. The cloudiness only lasts for a moment.

Chromic acid test (Thudichum).—When a small crystal of chromic acid is placed in a little normal urine, it dissolves without producing a precipitate. But in the presence of albumen the crystal produces a cloudy precipitate on its entering the fluid, and after its complete solution, all the albumen is precipitated in dark, reddish-brown flakes.

Albuminoid bodies treated with a solution of sulphate of copper and then warmed, after the addition of caustic potassa, or caustic soda, give the solution a beautiful violet color. This reaction does not appear, or only incompletely, when the alkali is added first.

Sugar and concentrated sulphuric acid produce a beautiful red color with all protein bodies, just as with the biliary acids.

Xantho-protein reaction (Legg).—The urine to be tested is boiled with nitric acid. If an albuminoid body be present the fluid becomes yellow, or a yellow precipitate is thrown down, and on cooling sodic hydrate, or aqua ammonia, changes the color to an orange-red.

Tannin test (Thudichum).—A watery solution of the purest crystallized tannin is to be used and should be prepared fresh for each testing. Healthy urine does not react with it. Albuminous urine gives a precipitate when brought in contact with it.

Neubauer and Vogel.—If albumen is heated with concentrated hydrochloric acid, or better, after the addition of a little sulphuric acid, a violet fluid results.

Equal parts of acetic and carbolic acids are recommended as a test for albumen.

Alum, corrosive sublimate, sulphate of copper, and tincture of galls, are mentioned as tests for albumen; also creosote, aniline, and other products of destructive distillation coagulate albumen (Thudichum).

The presence of albumen in a sample of urine is no *proof* of the presence of Bright's disease of the kidneys. *Every urine* containing albumen should be examined microscopically for casts, as the presence of these are needed to confirm our suspicions of this disease.

SUGAR.

When present in the urine, the sugar found is identical with grape sugar or glucose.

Normally the urine contains no sugar, some authors to the contrary notwithstanding. When present in diabetes mellitus, it is also found in the blood, vomitus, saliva, sweat, and, in fact, all the secretions and excretions.

Regular diabetic urine is generally of a pale or bright yellow color, large in quantity, acid in reaction, clear, and of a high specific gravity. In my own experience it has been the best looking urine I have had sent me for analysis.

To give all the tests for sugar, numbering, as they do, something over thirty, would require a great deal of time, besides being of little practical utility to the practitioner. I shall only mention some of the more prominent ones:

1. The most simple test is to boil down a quantity of the urine until the volume is reduced. Upon standing, the sugar separates from the solution in yellow, watery masses, which by recrystallization can be further purified.

Sometimes there is a sugar in the urine which is uncrystallizable and remains in a syrupy form.

2. The specific gravity alone, when 1030 or over, if the quantity of urine is over 1500 c.c. (50 fluid ounces) per day, and pale in color, affords a strong presumption of the presence of sugar.

In almost all of the following tests, if albumen be present, it must be precipitated by heat and removed by filtration.

3. *Moore's or Heller's test.*—One volume of urine is mixed with two volumes of liquor potassa and heated to boiling. If sugar be present, we have a color varying from a yellowish-red to a deep wine, according to the amount of sugar present. This test is the one most extensively used in Germany to detect the presence of sugar, and I consider it the best we have, as well as the simplest and most easy of application. The solution of caustic potassa should be fresh, as it might contain some lead from the glass, which would interfere with the test. Vogel suggests the following as a method of determining, from the more or less intense color produced by this reaction, the amount of sugar present:

If one prepare for himself solutions of grape sugar of different strengths, and make the tests with caustic potassa in tubes of the same size, he can easily form a scale of the percentage of sugar present, which will be fairly satisfactory. Treat two parts of each sugar solution with one part of caustic potassa, and heat to boiling. A one per cent. solution will be colored canary-yellow, a two per cent. solution dark amber, a five per cent. solution the color of dark Jamaica rum, and a ten per cent. solution becomes dark brown and opaque, while all solutions of less percentage are more or less transparent. As diabetic urine has a very light color, so by comparison with these solutions an approximative determination can be easily arrived at, with the help of the known specific gravity. If the urine is high-colored, it should be decolorized before applying *this* test, as well as Trommer's and Fehling's. To do this, put one or two ounces of the urine with half an ounce of animal charcoal into an eight-ounce vial, together with a pinch of carbonate of soda. Shake well for from five to ten minutes and filter; then carefully acidulate with acetic acid.

In performing this test it is well to fill the test-tube three-fourths full with the urine and liquor potassa, and heat the upper portion of it. In this way the slightest deviation in color may be easily noticed. The coloring matters of the bile, whether pure or decomposed, produce a brown color with caustic potassa, or caustic soda *without* the application of heat. We almost invariably get a precipitate in this test which is due to the earthy phosphate being thrown down by the alkalinity of the solution and heat.

4. *Böettger's test.*—This consists of adding to the urine in a test-tube enough carbonate of soda solution, caustic potassa, or caustic soda, to render the reaction distinctly alkaline, then about one grain (or a pinch) of subnitrate bismuth, and boiling. If sugar be present, the powder turns gray at first, and finally is reduced to the black metallic bismuth. Any of the sulphur compounds, if present, will also affect the reduction of the bismuth. To avoid this error, if we get a black precipitate, we take a second test-tube with the urine, and add as much oxide of lead as we did bismuth, first taking the precaution to render the reaction alkaline, as above stated. The litharge is only turned black by the sulphur compounds.

It is not affected by sugar. A simple gray color to the bismuth is no evidence of the presence of sugar; it must be black. This is an excellent test, and recommends itself to the physician on account of its simplicity.

5. *Mülder's test—Mülder-Neubauer, or Indigo.*—To a small quantity of urine in a test-tube we add enough of a solution of indigo to give the fluid a rather deep blue color, and then add enough sodic carbonate solution to render the reaction distinctly alkaline, and heat without shaking. If sugar be present, the color changes to a greenish, yellowish-red, red, yellow, and finally is almost entirley discharged.

Upon shaking the mixture up in contact with air, the blue color again returns. Upon standing, however, the solution eventually becomes almost colorless. If the amount of sugar be very small, the color becomes only a pale blue. This is a very good confirmatory test for sugar.

6. *Fehling's test.*—This is one of the best tests we have for sugar, its only disadvantage being the time and trouble experienced by the practitioner in preparing the solutions, especially if they are to be used for quantitative estimation, and their proneness to decomposition by long keeping. As you well know, two solutions are required, called, respectively, No. 1 and No. 2. The No. 1 solution is made by dissolving 51.98 grains of pure sulphate of copper in 500 grains of distilled water. No. 2 solution is prepared by dissolving 259.9 grains of pure crystallized Rochelle salt in a solution of caustic soda (specific gravity, 1.12), whose volume is equal to that of 1,000 grains of distilled water. One volume of No. 1 mixed with two volumes of No. 2 constitute Fehling's solution, 200 grains of which equal 1 grain of sugar (20 c.c.=0 1 d.g.) (Piffard). To use the above for qualitative work, we put a small quantity in a test-tube, dilute with about one-half its volume of water, and boil. If any change occur in the mixture upon being heated, the Fehling solution is worthless.

After the solution has boiled, and if it remains unchanged, we add two or three drops of the urine to be tested. If there be a considerable quantity of sugar present, the addition of the first few drops will be followed by a bright red precipitate of the suboxide of copper and this occurs after the addition of each succeeding few drops of the urine, until all the copper is reduced. It should not be concluded that sugar is absent from the urine till a volume of urine has been added in the above manner,

equal in bulk to the amount of Fehling's solution used. A good way to bring out the difference in color between the red suboxide of copper and the unchanged copper in solution is the following, recommended by Blitz: Mix with Fehling's liquid a concentrated sodium chloride solution, heat to boiling, and carefully add the urine to be tested.

The strong sodium chloride solution prevents a mixture of the two liquids, so that at their point of contact the red coloration appears with great distinctness.

If the urine should contain a *large* amount of sugar, it should be diluted before applying the copper tests.

7. *Trommer's test.*—This test is, I am sure, perfectly familiar to you all; yet, as it is the test most generally used in this section of the country, and one of the most unreliable ones, I shall give the method of its application and point out some of its defects.

To a small quantity of urine in a test-tube enough of a solution of sulphate of copper is added, drop by drop, to give the mixture a pale blue color. We then add about half the volume of liquor potassa and heat. If sugar be present, we have a precipitate of the red suboxide of copper.

In a concentrated urine we often get a red coloration, and always a precipitate of the earthy phosphates when present, which has many times been mistaken for the change in color due to the presence of sugar. If we bear in mind that this precipitate itself is never colored red, except by sugar, we remove the possibilities of a very grave error.

An excess of sulphate of copper is to be avoided, as if present we may have the formation of the black cuprous oxide. Sometimes the liquid changes color from blue to yellow; this occurs in the presence of small quantities of the cupric salt and large quantities of sugar, the cuprous oxide being held in solution by the excess of glucose (Witthaus).

The objections to this test are the following: Uric acid, sarcosin, mucus in excess, albuminous matters, especially peptone, kreatin, kreatinine, and pepsin, urinary coloring matters, and some other substances interfere seriously with the test. On this account it is much better to rely on tests whose sources of error are slight as compared to those of Trommer's.

8. *Fermentation test* (Witthaus).—We take three test-tubes, marked *A*, *B*, and *C*. In each place some washed yeast. Fill "*A*" completely with the urine under examination, and invert it, with the mouth below the surface of some of the same urine in a flat vessel. (To keep the air from entering the tube during its inversion, we place a finger over the mouth and hold it there till the open end of the tube is below the surface of the urine.) Fill "*B*" with some urine to which glucose has been added, and "*C*" with distilled water, and invert them in the same manner as "*A*"; "*B*" in saccharine urine and "*C*" in distilled water. Leave all three tubes in a place where the temperature is about 70° F., for twelve hours, and then examine them. If gas has collected in both "*A*" and "*B*," and none in "*C*," the urine contains sugar. If no gas has collected in "*B*," then the yeast is worthless; while if any gas is found over "*C*," then the yeast itself contains carbon dioxide (CO_2). In the two last cases the process must be repeated with a new sample of yeast.

9. *Roberts' fermentation test.*—This test is a quantitative one, and depends upon the loss in weight of the urine from fermentation.

Two flasks are filled with urine; one of these is tightly corked; the other, after the addition of some washed yeast, is fitted with a cork having grooves cut in the side, to allow the escape of carbon dioxide. Both are then placed in a temperature of 70° F. for twelve hours. At the end of this time the specific gravity of both are taken, and for every degree of specific gravity lost in the sample containing the yeast, Roberts calculates one grain of sugar to the ounce of urine.

This test is highly recommended by some writers and denounced by others. It has the disadvantage of occupying some time for its application, as well as the difficulty of always obtaining fresh yeast.

10. *Neubauer and Vogel.*—To a small quantity of urine in a test-tube we add a little weak ammoniacal solution of nitrate of silver, and boil for some little time. If sugar be present, we get a deposit of metallic silver, in the form of a polished mirror, on the bottom and sides of the test-tube. A good way to conduct this test, and one which I am in the habit of using, is to add to the urine a drop or two (according to its strength) of a solution of nitrate of silver, then enough aqua ammonia to clear up the thick, white, curdy precipitate of chloride of silver, and heat.

It must be borne in mind that tartaric acid, and some other matters, give the same reaction with this solution as glucose.

The test is chiefly important as a confirmatory one.

11. *Piffard's Cupro-potassic paste.*—This is prepared by taking of sulphate copper C. P., 1 part; crystallized Rochelle salt, 5 parts; sodic hydrate, 2 parts. Mix thoroughly in a mortar. The result will be a pasty mass which can be put in a wide-mouthed vial and kept till wanted. To use it, we take of the mass a piece about the size of a small pea, put it in a test-tube, add about two drachms of water, and boil till the mass is dissolved.

The solution has then a uniform pale and rather dirty blue color; we then add two or three drops of the suspected urine and boil again for a moment. If sugar be present, we have the usual reaction of the copper reduction tests.

12. *Pavy's solution for quantitative estimation.*

Take of Cupric sulphate.....	320	grains.
Neutral potassic tartrate.	640	"
Caustic potassa.....	1280	"
Distilled water	20	fl. ounces.

Mix.

The solution is made in the same manner as Fehling's, and 100 minims correspond to ½ grain of grape sugar. If wanted simply for qualitative work, it may be made by pounding together 5 grains cupric sulphate, 10 grains neutral potassic tartrate, and dissolving in 2 drachms of liquor potass. The usual blue fluid results. To use, we put a small quantity of the test fluid in a test-tube, dilute with four or five times its bulk of water, and boil. If upon boiling the solution remains clear, we then add the suspected urine, drop by drop, when if sugar be present, after the addition of a few drops, we have the red precipitate of the suboxide of copper. If a precipitate occur in the solution before the addition of the urine, it must be discarded, as it is worthless. The Pavy's solution, if kept for some time exposed to the light, deteriorates in the same manner as Fehling's.

13. *Tungstate of ammonium test* (Neubauer and Vogel).—We add to the urine a little caustic potassa solution, and then a few drops of molybdate, or tung-

state of ammonium, and heat to boiling. Then carefully acidulate with hydrochloric acid, when, if sugar be present, we have a beautiful blue color. My experience with this test is limited, but I hardly think it will commend itself to the physician, on account of the trouble found in obtaining the preparation of ammonium.

14. *Polarization test.*—Grape sugar rotates the plane of polarization to the right, and is therefore called dextrose. This method for the detection of grape sugar is one which can only be employed in a well-appointed laboratory, as a polarizing apparatus is a very costly affair, and one which it would be rare to find in the office of a practitioner.

15. *Campani's test.*—If one or two drachms of a copper acetate solution be heated to boiling in a test-tube, and urine containing sugar slowly added, the copper will be reduced to the red cuprous oxide—a one-half per cent. of sugar will cause a red coloration at the point of contact, and a one-tenth per cent. cause a yellow coloration.

16. *Knapp's method.*—This is performed by boiling an alkaline solution of mercuric cyanide with the urine under examination. If sugar be present, the cyanide is completely reduced to metallic mercury.

17. *Dr. L. S. Oppenheimer's test.*—The following solution is required for this test:

℞ Cupri sulphas..... gr. j.
Glycerinæ..... ʒ j.
M.

One drachm of this mixture will reduce one grain of grape sugar in the presence of a caustic alkali.

Two or three drops of the solution are put in a test-tube, and one-half ounce of liq. potassæ added; the whole is then boiled, a few drops of urine are added, and the whole boiled again. If sugar be present, it will be thrown down as the brownish-yellow cuprous oxide. It is claimed for this test that it is surer than Trommer's, it can be used to determine the quantity of sugar, and that albumen does not interfere with its working. The mixture will *not* keep indefinitely.

I believe this is one of the latest tests that have been given for sugar, as I have never seen it mentioned in works on uroscopy, and it has only lately appeared in the periodicals. I have not yet had time to investigate as to the value of this reaction, but if all is true that Dr. Oppenheimer claims for it, I cannot see why it should not be one of the very best tests we have at our command.

18. *Bouchardat's test.*—This test is supposed to be applicable to the urine even in the presence of albumen, and is as follows: Take fifty cubic centimetres (3x.) of urine and add to it a heaping teaspoonful of slaked lime. Boil over an alcohol lamp or a Bunsen burner. If there is sugar in the urine it acquires a yellow or dusky hue, according to the quantity of sugar present. If there is but little sugar present there is simply a brownish hue.

When the oxide of several metals, as copper, mercury, silver, gold, or bismuth, in the form of salts, are brought in contact with solution of grape sugar at high temperatures, a reduction of the oxide to a lower oxide, or to the metal, takes place.

The great value of knowing several of the different tests, for both albumen and sugar, is to enable the practitioner, when suspicious of the presence of one or the other of these substances, to apply several reactions to the same specimen of urine, whose coincidence will establish the fact of the presence of albumen or sugar in that urine, or whose entire failure to agree will prove the absence of the same.

Before closing, I wish to impress on the minds of the members of this Society the *great* importance of the examination of the urine in *every* case of sickness or deviation from health, and *more especially* in cases where the *slightest* doubt as to the diagnosis exists.

Even though, by an examination of the urine, we are unable to throw any light on our case, still we have one satisfaction: that of being able to exclude the kidneys from participating in the trouble. In my humble opinion, a council should never be called (except in cases of emergency) without first having had a full analysis of the urine made. This may to some seem unnecessary, but when we consider that the slightest febrile action, or catarrh, changes, to a more or less degree, the normal composition of the urine, we find a ready excuse for being so particular.

Reports of Hospitals.

NEW YORK HOSPITAL NOTES.

SERVICE OF DR. WILLIAM H. DRAPER.

ABNORMALLY LOW TEMPERATURE FROM COLD.

THE patient was a male, about forty-five years of age. No history. Was brought in on the morning of January 23d, comatose and pulseless, having been found in this condition in a hallway. It was not known whether he had been drinking. At 6 A.M. pulse was 42; respiration, 13; temperature, 87°. Coma complete; patient could not be aroused therefrom. On examination, patient was very thin, poorly nourished, and both legs were œdematous and swollen. Feet icy cold and blue. There was slight automatic movement of the left arm. Respiration slow and weak; breath not very alcoholic; no cardiac impulse. The radial artery was pulseless, and had the feel of a cord; the femoral gave a slight feeble pulse. Pupils not dilatable. Conjunctiva still sensitive, giving slight reflex in the eyelids. Otherwise all response to reflex excitation completely lost. The skin over the entire body was dry and cold to the touch. Patient had several large and protruding hemorrhoids. Urine dark-colored and scanty; one and a half drachm drawn by catheter contained amorphous urates and albumen.

Patient was immediately sponged with tepid mustard-water, and placed in the hot bath, with hot bottle applied to the feet. Spts. vini. gall., ʒ j., and digitaline, gr. $\frac{1}{44}$, given. At 9 A.M. respiration was somewhat improved, and pulse better. A vigorous slap on the cheek now brought reflex action. At 12 M. temperature 85°, taken in the rectum and urethra. At 1 P.M. patient could be aroused; sensibility had returned to a certain extent. The insertion of the hypodermic needle gave rise to pain. At 1.30 P.M. ether and spts. vini. gall. given; also digitaline, gr. $\frac{1}{24}$. At 2 P.M. temperature in the rectum 93°. Instances on record of collapse from severe injury, hemorrhage, etc., gave even a lower rectal temperature than the 85° obtained in this case, but Dr. Draper had never before seen such a low temperature as this from cold. At 3 P.M. patient was still in the hot-air bath. Though partially comatose, he was so far restored as to be able to respond

when spoken to, but immediately subsided into a state of unconsciousness. Some reflexes had also returned, and there was considerable tossing about of the arms and occasional muttering.

Treatment.—The main reliance was in alcoholic stimulation and digitalis.

The patient died on the same night. Autopsy showed fatty liver, with renal disease.

RARE CASE OF CHYLOUS URINE.

The patient was a male, aged thirty-seven. Admitted February 8th, and giving the following history: Is a native of the West Indies; inheritance good. When seventeen years of age he was thrown from a horse. Did not strike the head, but sustained a severe injury of the right side. This brought on a severe cough with expectoration, and patient lost in health. A few months later he took a trip to Copenhagen. During the first three weeks of the voyage he was very sea-sick, and had several boils. At the end of that time he was suddenly troubled with difficult micturition. He then passed a small hard lump, followed by milky urine. The patient has never had stricture or gonorrhœa. During the rest of the voyage he improved considerably in health and gained flesh, but continued to void milky urine. In Copenhagen he immediately obtained medical treatment, and urine soon returned to a nearly normal condition. He then had an attack of scarlatina, after recovering from which he passed normal urine. Patient returned to the West Indies, and remained in good health for several years. In October, 1871, while out walking, he was suddenly compelled to urinate, and after much difficulty a hard viscid lump was passed, coming away with such force as to adhere to the fence against which it was projected with the stream of urine. This was again followed by milky urine, which continued for three months. He then had phlebitis of the right leg.

In May, 1872, patient took nitre, etc., and had his bladder washed out three times a day, with very little relief. Urine continued more or less milky up to 1874, when patient came to this city. In May, 1874, he passed another lump. This was again succeeded by milky urine. Was treated, but derived no benefit.

In June, 1875, patient again obtained medical advice. At times small quantities of soft coagula would pass from the bladder, often causing extreme retention and suffering, which was only relieved by the hot bath, opium, etc. At intervals he would pass hard lumps similar to the ones mentioned. At this time his urine, shortly after being discharged, would coagulate into an opaque, jelly-like clot. Urine was always acid, albuminous, coagulable by nitric acid, and contained oil, eight grains to the ounce. Under treatment patient rapidly improved. Oil of turpentine increased the urine, diminishing the amount of oil. In three weeks urine was very much better, and soon became natural. Patient does not drink to excess. Bowels relaxed; appetite capricious. He has taken large doses of morphia and chloral. Six weeks ago several sores appeared on the buttocks, made worse on lying down. Patient never had yellow fever.

Dr. Draper remarked that the history was typical of a rare disease, one which for years was unexplained. The patient had recently had a recurrence of his trouble, and the fluid now passed was an excellent specimen of chylous urine. It had an opaque, pinkish-white appearance, and was of the consistency of ordinary milk. It was mixed with the contents of the blood-vessels as well as those of the lymphatics.

Sometimes, and especially on standing, instead of its constituents being evenly disseminated as in a specimen just drawn, a tremulous mass subsided to the bottom of the glass. This again broke up, furnishing a creamy scum which rose to the surface, and a pinkish or brownish sediment.

Examined microscopically, the urine was found to contain, besides the usual ingredients, a substance which in all respects was similar to chyle, and composed of oil and fibrin, but always mixed with pus, often with blood.

Sometimes partial coagulation took place within the bladder, and the resulting masses caused serious retention.

This affection was formerly supposed to be due to a rupture of the lymphatic vessels of the urinary organs. Dr. Bilharz, of Cairo, was the first to describe this kind of urine; hence the Bilharzia hematobia.

It was afterward found that the disease was dependent on the presence of a microscopical blood-worm, which existed in innumerable quantities in the circulating fluid. It had previously been discovered in the urine in hematuria and chyluria, but its presence in the blood was first noticed by Dr. Lewis, of India, in 1872.

In this case, since admission, his blood had been examined, and his worm, the *filaria sanguinis hominis*, had been found in large numbers. A curious fact connected with it was that the worm is only developed during the night. But if the patient (as has been shown in this case) was, by work or otherwise, deprived of sleep at night, obtaining his rest during the day, the filaria was then only found in the daytime and not at night; *i.e.*, its presence was noticed only during the periods of sleep.

Another strange feature was that the mosquito sucks these animals (by preference) from the blood. Greater numbers were found in a certain quantity of blood drawn by the mosquito than in the same quantity in the circulation. These were evacuated in a condition capable of communicating the disease to another (through drinking-water).

The worm varied in length from $\frac{1}{150}$ to $\frac{1}{36}$ of an inch, and was about $\frac{1}{3500}$ of an inch in diameter.

The mechanism of the production of chylous urine consisted ultimately in the formation of minute openings in the urinary tract, in communication with the lymphatics, and in this way establishing chylous fistulæ, which give rise to the phenomenon of chylous urine.

The subjective history showed that the patient had suffered from this disease for the past twenty years, but during this period he had had several intermissions of apparent health. Whether during these intermissions the filaria had disappeared from the blood or remained in the system, it was impossible to say. The latter was probable.

The patient was taking oil of turpentine, gtt. xx. t.i.d.

ANTIPYRETICS, ETC., IN TYPHOID FEVER.[1]

The fever in typhoid is naturally a very exhausting one. The patient emaciates rapidly, because of the active combustion of the tissues, due to the high temperature. When the fever is at its height, the patient usually assumes the dorsal decubitus, and

[1] Clinical Lecture by Dr. William H. Draper. Delivered at the New York Hospital, February 2, 1882.

shows all the signs of supreme exhaustion. There is no muscular movement, no expression in the features, but a vacant and dull look. Sordes collect on the lips, teeth, and nostrils.

The fever is simply the using up of the patient, consuming the energy that is set free. Hence, for each degree of reduction the danger is correspondingly lessened. To reduce the temperature is, therefore, the most essential feature.

Proper adjustment of the clothing, proper attention to food and drink should always receive careful attention. Besides their cooling effects, drinks also facilitate peristalsis, and assist in removing matters produced in the retrograde movement. It may even be necessary to act on the bowels to depurate the system of these effete materials.

Rest.—Rest is absolutely essential. The patient should be protected from any source of irritation, and there should be no muscular movements whatever. This should be insisted upon, as patients often exhaust themselves greatly during the early stages of the disease, and thus lessen materially their chances of recovery.

Diet.—A milk diet is the best in the great majority of cases. Some patients cannot take a purely milk diet for a long period. In such instances animal broths may be given. But these must be fluid, concentrated, and rich in all the elements of animal fibre, and not merely a solution of a few salts with extractive matters.

Quinine.—Extraordinarily large amounts of this drug are needed. The striking effect of quinia shown in this patient cannot be looked for in small doses. In other fevers, *e.g.*, malarial, surgical, etc., quinine thus administered exerts its specific power, but moderate doses in typhoid fever produce no such effect.

Alcohol.—In regard to alcohol as an antipyretic in typhoid fever, and in fact all high grades of temperature from any cause, there can be no question of its ability. Alcohol is an antipyretic in that it does reduce the temperature. At the same time its action in fevers is explained not only by its antipyretic effect, but also by its stimulating and supporting the heart, and by supplying something, a "food," out of which force is eliminated for the vital functions. Hence its utility in fevers. It is a very unstable hydrocarbon, and is, therefore, very combustible. In the body it has the same combustibility, and thus eliminates energy and obviates the loss and exhaustion resulting from the combustion of the patient's tissues. The same would obtain of any food, the latent force becoming the active energy of the body.

One of the most striking effects of alcohol is the almost utter impossibility to intoxicate in high fever. When alcohol circulates in the blood, when it produces its specific effect, it intoxicates. But when consumed like any other food, this specific action is not shown.

The power to digest alcohol varies in different persons. In some a teaspoonful may cause intoxication. Others take large quantities in health and experience no effect whatever. This is principally due to a greater power of digestion for alcohol. The same is found even for ordinary foods. In febrile conditions, however, the ability to consume is uniform. In typhoid and similar fevers a patient will take large quantities of alcohol (even a quart of brandy in twenty-four hours) without any of the usual symptoms of alcoholism, any of the cerebro-spinal effects, or even any odor upon the breath. Also, the patient is not only not rendered delirious but the delirium is quieted by alcohol; he thus obtains possession of his senses by those means which under other circumstances would deprive him of them. This action of alcohol is of specific value, not only in typhoid but in all fevers, and at all ages. Even infants are able to tolerate doses in fever that would otherwise set them wild.

There is only one explanation of this. Alcohol being very combustible is oxidized and split up by the fever into its elements, H_2O and CO_2, water and carbon dioxide, thus by its decomposition liberating its potential force and saving combustion of the patient's tissues.

The feeding of fever, therefore, constitutes one of the most important elements in its treatment. For this purpose alcohol as a food is most easily disintegrated and yields most readily its power. Hence it is indicated in all continued fevers when the patient is suffering from the effects of combustion.

Alcohol also stimulates the nervous centres. The heart becomes more steady and firm, and the first sound, which may have been feeble or absent, becomes distinct. By its stimulating effect it will also quell the delirium and control the locomotor disturbances. In the use of alcohol in fever, it is important to bear in mind the indications for its administration.

Alcohol is required when the patient exhibits symptoms of great nervous prostration, with subsultus, delirium at night, jactitation, with a position in bed indicating great physical debility, and a very dry tongue; all coming on with the increase of temperature.

If alcohol be administered it will quiet the delirium and the locomotor derangements; the patient will sleep quietly, the tongue will become moist, and the whole aspect of the case will be changed for the better. If, however, it increases the frequency of the pulse, if the delirium becomes more active, the tongue more dry, the skin hot and parched; if the motor spasms, tremulousness, subsultus, and restlessness are aggravated by alcohol, it is doing harm.

In all cases it is important that the temperature fall and the pulse become less frequent until regulated from one twelve hours to another. In regard to the administration, the potent property lies in the amount of alcohol. Brandy or whiskey is preferable to fermented preparations. It is exceedingly desirous to prevent anything like fermentative dyspepsia, hence wines and especially beer should be avoided. Old wines were thought to be excellent. Alcohol does the good, however, and the simplest way is the best. It is best taken with the food; given with milk it is thus diluted and rendered bland.

The amount of alcohol to be administered varies with the patient. This consideration needs careful and intelligent observation of the symptoms. There is no strict law. It should be given until the desired effect is obtained. The amount usually ranges from ℥iv. to ℥xxiv. But in the majority of cases it will be necessary to give the largest quantity in the twelve hours from 6 P.M. to 6 A.M. During this period all the vital powers, the respiration, pulse, and temperature reach their lowest. Therefore the greatest failure in these hours need the greatest amount of stimulation.

In typhoid fever many symptoms may arise which require special attention. Insomnia may be exceedingly distressing, and, as a rule, opium may be used in moderate doses. It not only produces sleep

at night, but helps the patient to bear the exhaustion.

Diffusible stimulants, ammonii carbones, etc., may also be needed. Digitalis may be necessary to help tide over the dangers.

MANAGEMENT OF THE ACCIDENTS IN TYPHOID FEVER.

Certain complications may occur in the course of typhoid fever. The principal accidents which may imperil the patient are (1) congestion of the lungs; (2) perforation of the intestine; (3) perforation of a blood-vessel. All these require special attention.

1. Cough is almost always present, dependent upon a moderate degree of bronchial catarrh. There is always more or less congestion at the base of the lungs, owing to the feeble circulation, the dorsal decubitus, the weakened muscular fibres, and shallow breathing. A good plan is to have the patient sit up for a while, or change his position, in order that by forced inspiration the lungs may become more inflated than otherwise. It is always necessary to increase the force of the heart's action. Oil-silk jackets may be used, or the patient can be wrapped in cotton. If the bronchitis is severe, dry cups should be applied.

2. The symptoms of intestinal perforation are acute pain, accompanied by rigors; a sudden prostration, and a very remarkable degree of collapse. This accident makes the prognosis more serious. It is possible to produce a reaction sufficient to set up a peritonitis; nevertheless, as the patient is in a state of collapse and in immediate danger, stimulants and opium are indicated. Opium has a most beneficial effect on the heart, and should at once be given hypodermically, to insure a speedy effect. There is no use in applying leeches, blisters, etc.

3. Blood in the stools, indicating that a blood-vessel has been perforated by one of the ulcerating Peyer's glands, is a grave and serious symptom. Absolute repose should be obtained, and the diarrhœa, and even the patient's desire to defecate, be controlled if possible. Opium is, therefore, indicated. Styptics should be administered per anum. These do no good by the mouth, as the lesion is situated so far down the intestine.

PUSTULA MALIGNA—TREATMENT BY IODIZED INJECTIONS.—Dr. Poladura, in *La Revista de Medicina y Cirugia Prâticas*, relates the following case of malignant pustule, apparently cured by the hypodermic use of iodine. The patient was a shepherd, aged forty-one, of sanguineous temperament and good constitution. Five days before he was seen, he presented the local and constitutional signs of malignant pustule of the face. The treatment consisted in incisions, excisions, the actual cautery, and antiseptic and emollient applications. During the next two days following, the œdema and induration had attained such a degree as to constitute a veritable monstrosity; the temperature was 40° C., and there was vomiting and great prostration. Tincture of iodine was given internally, and antiseptic applications continued. Ten hypodermic injections of a two per cent. solution of tincture of iodine were administered around the zone of induration. Subsequently the symptoms became aggravated. Injections were again practised in various locations in the œdematous region. The next day the delirium, as well as the sweats and chills, had disappeared, and the pulse was stronger. An inflammatory circle was visible at the margin of the eschar. Treatment being continued, a cure resulted.—*Rev. de Ciencias Med.*, June, 1882.

Progress of Medical Science.

GLUCOSE AS A DIURETIC.—Dr. Vandani (*Gazetta Médica di Torino*) has made a series of observations in regard to the diuretic action of glucose, introduced per rectum or subcutaneously. The following are some of the results obtained:

Observation I.—Muscular rheumatism. Woman, aged twenty-four. May 24th, enema of glucose, twenty-three per cent.; urine in twenty-four hours, 2,620 c.c. May 24th, enema of glucose, twenty-five per cent.; urine in twenty-four hours, 2,620 c.c. May 25th, no treatment; urine in twenty-four hours, 1,850 c.c. May 26th, no treatment; urine in twenty-four hours, 1,810 c.c.

Observation II.—Facial erysipelas. Woman, aged seventeen. May 23d, no treatment; urine not measured. May 24th, no treatment; urine in twenty-four hours, 1,320 c.c. May 25th, two enemata of twenty-three per cent. of glucose; two enemata of twenty-eight per cent. of glucose; urine in twenty-four hours, 2,705 c.c. May 26th, no treatment; urine in twenty-four hours, 2,010 c.c. May 27th, no treatment; urine in twenty-four hours, 2,220 c.c. May 29th, no treatment; urine in twenty-four hours, 1,340 c.c.

Observation III.—Bronchitis. Hysterical woman, aged seventeen. May 23d, two enemata, twenty-five per cent.; two enemata, twenty per cent.; urine in twenty-four hours, 4,145 c.c. May 24th, no treatment; urine in twenty-four hours, 3,625 c.c. May 25th, no treatment; urine in twenty-four hours, 2,775 c.c. May 26th, no treatment; urine in twenty-four hours, 2,100 c c. May 27th, no treatment; urine in twenty-four hours, 2,050 c.c.

Observation IV.—Anchylolostoma, anæmia. Man, aged forty. June 11th, no treatment; urine in twenty-four hours, 1,615 c.c. June 12th, three enemata, seven per cent.; urine in twenty-four hours, 2,400 c.c. June 13th, no treatment; urine in twenty-four hours, 1,910 c.c. June 14th, no treatment; urine in twenty-four hours, 1,490 c.c.

Observation V.—Mitral insufficiency. Woman, aged sixty-five. June 7th, no treatment; urine in twenty-four hours, 885 c.c. June 8th, eight subcutaneous injections, seventy per cent.; urine in twenty-four hours, 1,325 c.c. June 9th, no treatment; urine in twenty-four hours, 870 c.c. June 10th, nine injections, seventy per cent.; urine in twenty-four hours, 1,405 c.c.

Hypodermic injections seem to be preferable to enemata, on account of their more certain action. Clysters are often ineffective because unfavorable intestinal conditions do not permit absorption.—*La Indep. Med.*, June, 1882.

SUBCUTANEOUS EPHEMERAL NODOSITIES OF RHEUMATISM.—MM. Troisier and Blocq (*Revue Mensuelle de Médecine*) publish an interesting instance of this rare affection, as described by Froriep and Jaccoud. It manifests itself in the following manner: Small subcutaneous tumors appear, sometimes as elevations more or less marked, and sometimes only discoverable on palpation. In shape they are spherical or ovoid, and ordinarily well circumscribed. Their volume is variable; it is commonly compared with that of a grain of wheat, a lentil, a pea, or a hazelnut. They offer a peculiar resistance to the finger; they are firm and rather more elastic than hard. They are more or less movable under the integu-

ment to which they are generally non-adherent. Most frequently they are but little sensitive to pressure, but pain is sometimes experienced. They may appear upon any portion of the body, either in the neighborhood of joints, remote from the diseased articulations, as on the head (they occupy by preference the frontal and occipital region), or may be met with upon the ear. Their number is very variable; they often appear in successive crops. Their evolution is altogether characteristic; they develop rapidly, and in short time acquire their largest dimensions; they disappear after a number of hours or days without leaving a trace. In the observation detailed by MM. Troisier and Blocq the affection showed itself during the decline of an attack of acute articular rheumatism. M. Féréol states that on several occasions, during fifteen years, he has seen these superficial nodosities in a lady. They were formed from day to day, and appeared upon the forehead. They presented themselves as rounded eminences, of elastic hardness and regular contour. They caused no discoloration of the skin, and were not sensitive even to strong pressure; they were unaccompanied by itching, pricking, or heat. These nodosities, which vary in size from a hazel-nut to a pea, were never very numerous; sometimes there was one, sometimes there were two or three, never more. When there were several of them they were unequal and situated at different levels without symmetry. These nodules appeared upon the patient's awakening. They originated during the night without producing any malaise. In fifteen years this phenomenon was repeated twenty-five to thirty times. The lady otherwise enjoyed good health. She was descended from an arthritic family. She had never had rheumatism up to date, but was suffering from a rebellious pityriasis of the scalp. She was also subject to migraine, appearing about once a month. It was impossible to connect the appearance of these nodosities with her menstruation, but it appeared to bear a relation to the migraine, with the attacks of which it often coincided. M. Féréol, who has observed other analogous cases, made a report of the subject to the Scientific Congress of 1879. It is difficult at present to state precisely the anatomical seat of these tumors. M. Troisier supposes them to be developed in the fibrous tissues—periosteum, ligaments and aponeuroses—and sustaining to the subcutaneous connective tissue only the relation of contiguity.—*Journal de Médecine*, January, 1882.

Sulphocresylate of Sodium.—A year ago, M. Rabuteau announced that the sulpho-phenate of sodium was an energetic purgative, and could be kept unchanged in solution. M. Rabuteau now brings forth the sulphocresylate of sodium. Cresylic alcohol (C_7H_7) HO may be derived from tar; treated with sulphuric acid it yields sulphocresylic acid (C_7H_7) H SO_4. This acid has a saline taste. Treated with perchloride of iron it strikes a beautiful violet color. Six grammes of this substance have been ascertained to produce no effect upon a dog of medium size.—*La Tribune Médicale*, June 25, 1882.

Rhinophyma.—Hebra (*Vierteljalisch für Dermatologie und Syph.*) has excised specimens in two cases of rhinophyma and examined them anatomically. The peculiarity of the neoplasm consists in the fact that it represents only the normal constituents of the skin, but in abnormal proportions. The epidermis and rete malpighi are not changed. In the cutis, on the other hand, there is a very marked increase in size of the connective tissue fibres, the sebaceous glands are enlarged, and are composed of a greater number of lobules, and many dilated vessels are visible. The fibres included between the glandular lobules contain young nucleated connective tissue. The author regards them as primary in the neoplasm, in so far as they are true formative elements.

The process is, therefore, to be considered as a hyperplasia of the skin in all its parts, with the exception of the epithelial structures covering the derma. It is to be differentiated from elephantiasis arabum, which is always accompanied by inflammatory phenomena and chronic œdema. On the subject of operative procedures the author only alludes to the statements of Sennert and Chausit. In cases operated upon, some by his father, some by himself, everything deforming the nose was simply removed, without covering the loss of substance. Recovery was always complete. Hemorrhage during this procedure is intense, and to it is often due, the author acknowledges, the failure to complete the operation in one sitting. Hebra might have overcome this difficulty if he had known the galvanocaustic method of Bröer. By this means two cases were treated at the Clinique at Breslau without loss of blood, and with complete success.—*Centrablatt für Chirurgie*, June 24, 1882.

Operative Procedures in Carcinoma and Adenoma Uteri.—In describing a case of adenoma of the uterus, Rokitansky (*Allg. Wiener med. Zeitung*, 1882, No. 13) takes occasion to express his views generally in regard to operations for carcinoma uteri. According to him, the prognosis in this disease is absolutely unfavorable. Scraping and subsequent injection of fuming nitric acid might afford amelioration for a time, but recovery was impossible. Rokitansky is a decided opponent of total extirpation of the uterus. It occupied a position analogous to that of transfusion. When the latter was indicated, it was without avail; when performed without necessity, it was of course superfluous. The patient gained nothing by a total extirpation of the uterus. When other surgical procedures seemed fruitless or inexpedient, where less severe operations were capable of removing the diseased tissue, total extirpation would seem an inhuman measure, jeopardizing the woman's life. The prognosis of adenoma was favorable, but carcinoma was not infrequently developed from it. For scraping out the uterus, Rokitansky prefers the curette to Simon's sharp spoon. The patient is placed on the left side. He begins with the most delicate curette of the thickness of an ordinary uterine sound, and gradually employs the larger ones. He never enlarges the cervix previous to using the curette. In decided flexions of the organ, he inserts a tenaculum into the cervix, and overcomes the deformity by traction. Only in very sensitive persons would narcosis be found necessary.—*Centralblatt für Gynäk.*, June 24, 1882.

The Ergotine Treatment of Uterine Tumors.—In the July number of the *New York Medical Journal and Obstetrical Review* Dr. William T. Lusk, Professor of Obstetrics in Bellevue Hospital Medical College, relates a case of fibro-myoma of the uterus in which ergotine injections into the subcutaneous tissue of the abdominal wall over the tumor, not into the tumor, resulted in a rapid diminution in the bulk of the growth, at the expense, however, of gangrene of the compressed tumor, ending in fatal septicæmia.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, August 19, 1882.

CONCERNING COTTAGE HOSPITALS.

Dr. Lucius W. Baker, of Baldwinsville, Mass., in a paper read at the recent meeting of the Massachusetts State Medical Society, very strongly advocates the establishment of cottage hospitals in different parts of his State. The idea is a good one, and deserves due consideration on the part of the profession who practise in rural districts. Not only in Massachusetts, but in every other State in the Union there is a great scarcity of hospital accommodation outside of the large cities. It need not be said that for the lack of just such care and attention as could be obtained in a small, conveniently situated hospital many cases of accident have proved fatal. The same may be said, in a less degree, of medical cases requiring careful nursing and the constant watchfulness of a medical attendant. It seems strange, when there is hardly a rural practitioner in any populous neighborhood who has not wished for some accommodation for his sick poor and for his cases of accident, that some active measures have not been taken to secure the end in view.

The utility of these smaller hospitals has been demonstrated in a very practical manner in Great Britain, and there is no reason why such experiences should not be repeated here with even greater benefit to the class for which they may be established. Since 1859, when the first village hospital was projected at Cranleigh, Eng., there have sprung into existence over two hundred and fifty institutions, more or less widely disseminated over that country. It is estimated that fully fifty thousand worthy patients are annually ministered to by these means. These cottages are generally small, inexpensive in equipments, and are provided with a medical staff and nurses. The expenses of their maintenance are partially borne by the patients themselves, the deficit being made up by voluntary contributions of neighboring citizens and others.

There can hardly be any argument against the cottage hospital plan, when the latter is applied to large villages remote from metropolitan centres. Cases are constantly occurring in the former districts requiring just such treatment as can be obtained in the smaller hospitals. But not only would the patients be benefited by the care which they would thereby receive, but the physicians of the neighborhood would be relieved of an immense amount of drudgery in caring for their sick poor, scattered far and wide over their rides. The following remarks by Mr. Burdett ("Cottage Hospitals," pp. 163, 168) not only places this matter in its proper light, but gives some idea of the practical manner in which these institutions are managed:

"The country practitioner is a distinct gainer by the cottage hospital. It economizes his time and labor. The great difficulty with which a country doctor has to contend is the wide area he must cover in the course of one day's round. In bad cases, when more than one visit is necessary in the course of the day, the same ground has to be traversed twice, however carefully the visits may be managed.

"Now, however, it has become the rule at the majority of cottage hospitals, to appoint one member of the staff, either permanently or, where more than one practitioner resides in the village in which a cottage hospital is established, two or more in rotation a certain number of weeks or months, whose duty it is to look after all the cases in the institution that require special care, and to give him the title of medical director, or medical officer. By this means, when a severe case requiring constant attention and frequent visits occurs in the practice of a country doctor, it is, as a rule, removed to the hospital, and thus all difficulty and anxiety of the especially harassing kind before alluded to is obviated.

" . . . The duty of the medical director is not to initiate new systems of treatment for any but his own patients, but to carry out the wishes and views of his colleague, who would visit his own patients daily, and order any alterations which he may deem necessary or advisable."

Considering the simplicity in their construction, the cost of establishing these hospitals need not be great. The State Board of Health of New York, in a recent tract (No. 27) on the subject of temporary refuges for contagious diseases, gives some very simple plans of hospital construction which have the additional merits of cheapness and adaptability to the requirements of any community in any locality. But there is hardly a physician in any of the larger towns who is not competent to advise any committee or local health board not only as to situation, but as to plan of construction of these useful cottage hospitals.

THE INOCULATIVE FUROR.

THE idea that specific infectious diseases may be prevented or modified by vaccination has now obtained a remarkable grasp upon the imagination of pathologists. We present a list of what it has already been asserted can be done. Chicken cholera can be prevented by inoculating cultivated virus, says Pasteur. Anthrax can be made harmless in the same way. Rabies can be prevented by intravenous injection of the virus, according to M. Galtier, who has made a number of experiments upon sheep and dogs. Tuberculosis can be prevented, in time, in three different ways.

Dr. Wesley Miller avers that the virus of bovine tuberculosis, after being attenuated by cultivation in heifers, can be used safely as a vaccinating material upon the human body.

Dr. Robert Koch supplies to an imaginative English physicist materials for a theory by which tuberculosis is to be prevented. The cultivated bacilli are simply to be injected into the tissues of possible consumptives.

Most beautiful of all, Dr. T. H. Buckler, of Baltimore, Paris, and Boston, announces an antagonism between typhoid fever and pulmonary tuberculosis. This he tries to prove by citing cases of incipient phthisis, which recovered after having an attack of typhoid fever; also by various mortality statistics. Dr. Buckler would have persons inoculated with typhoid fever, perhaps by means of infected milk. The seeds of consumption would thus be driven from the system of those who survived. M. Aubert suggests a way to ameliorate or prevent the development of syphilis in persons who have an initial sore. His plan is based upon Galtier's experiments with rabies virus, and consists in injecting a little of the secretion from the sore directly into the veins of the patient. An ingenious, *à priori* argument is offered in the fact that a mother with a syphilitic fœtus sometimes seems to receive the disease in a mild form, or even to be made proof against it.

Out of all this inoculative activity no doubt much good will eventually come. But it must be admitted that the breezes of medical fashions stir up a great deal of chaff.

THOUGHT-READING AND BRAIN WAVES.

SOME time ago we chronicled the organization in England of a Society for Psychical Research. The name suggests an affinity to such institutions as the Institute for Prenatal Culture. The society in question, however, is a legitimate one, and contains many members who have an established reputation in scientific circles.

One of the first pieces of work done is a report to the council upon the so-called muscle reading. The investigation was made by three gentlemen: Professor Barrett, Mr. E. Gurney, and Mr. F. W. H. Myers.

They cite some interesting cases illustrating the exquisite tactile sensibility of some persons who are muscle readers. Thus a young lady could write words, or even rudely copy sketches which had been shown to her mother, and not to herself, the mother sitting behind her and placing a finger upon the girl's bare arm above the flexed elbow.

The chief object of the report, however, is to bring out for discussion the question whether there are not cases of alleged "thought reading," which cannot be explained by the theory of muscular sensibility. Scattered instances, says the report, pointing to an affirmative answer, will be encountered by those interested in the research. A number of instances are cited seeming to show the inadequacy of the muscular impression theory. An eminent *savant*, for example, was able to make his daughter do certain things fixed in his mind, even when there was no physical contact.

The *piece de résistance* of the report, however, consists of an account of an investigation made regarding the alleged thought-reading powers of a clergyman's family near London. This family was visited and studied, not only by the committee, but by Professors Balfour Stewart, A. Hopkinson, and others. The children of the clergyman in question consisted of five girls and one boy. They ranged in age between ten and seventeen years. They were all healthy and not in the least hysterical.

The experiments with them consisted in sending one of them from the room where the investigators sat. They then chose a card or a name. The child then returned, and, after thinking a moment, would in most cases guess the word selected correctly. Among three hundred and eighty-two trials there were two hundred and two successes. It was the object of the investigators to preclude every source of deception. The details of their precautions need hardly be given here. The character of the men and of the journal (*The Nineteenth Century*) in which the experiments are recorded makes it impossible to think that there was any conscious deception. The accounts given have some scientific value. Nevertheless, it is acknowledged that almost every instance of so-called "mind-reading" is really due to muscular sensibility, or a peculiar capacity to interpret facial expression. It would be illogical to refer a few apparently exceptional cases to a different law without extremely weighty evidence. The gentlemen who have made this psychological research do not appear to realize the involuntary capacities of the human organism.

JUVENILE SMOKING.

A VAST amount of evil has followed from the apparently trivial practice, introduced by tobacco-sellers, of "breaking" cigarette packages. We learn that in this city, at least, a most profitable part of this trade consists in peddling out cigarettes to

youths of all ages. School boys, store boys, cash boys, and the crowds of young gamins that wander about the street, furnish this demand for a penny's worth of cigarettes. The result is that an early habit of smoking is acquired; and, furthermore, of smoking tobacco that is rarely pure, and is often injuriously adulterated. Refuse cigar-stumps, valerian, opium, saltpetre, sulphuric acid, bromide of potassium, potato-leaves, and ammonia are some of the ingredients used in "tinkering" the tobacco of cigarettes.

It was with much regret that we learned of the failure to pass a bill last winter forbidding the sale of cigarettes, except by whole packages. Whether such a law would be constitutional and practicable or not, its enactment would at least draw attention to the existence of a growing evil, and one with which it is necessary to deal promptly.

Tobacco is a poison which acts with especial certainty upon the immature organism. It impairs nutrition, and in particular that of the nervous system, laying the foundation for subsequent nervous troubles of various kinds. The bad effect of its use, in the form of cigarettes, upon the sexual organs, prematurely stimulating them, is quite generally conceded.

There is in France a Society to Prevent the Abuse of Tobacco. In England, a Society for the Suppression of Juvenile Smoking has just been organized. Some similar agency might be of use in this country. At any rate the family doctor should do a little lay preaching upon this matter of juvenile smoking.

THE PREVENTION OF BLINDNESS.

The attention of sanitarians has heretofore been but slightly directed to the prevention of blindness, although the general subject of the hygiene of the eyes has often enough been discussed. A society has been formed within the past two years, however, in London, for the purpose of preventing blindness and ameliorating the condition of those suffering from that affliction. We are told by those interested in this organization that there are about thirty-one thousand blind persons in Great Britain, or 1 per 1,000 inhabitants. Of these it is estimated that at least two-thirds might have preserved their eyesight if proper care had been given it during infancy or later.

The cost to support the thirty-one thousand blind is said to be £310,000 sterling annually. To this direct expense there must be added the loss of the productive work which these persons might have done. So that the prevention of blindness is an economic as well as sanitary problem.

One of the first things attempted by this society was the offering of a prize for the best essay upon the means for preventing blindness. It has also attempted to instruct parents regarding the dangers to the eyesight which their children incur. Ten thousand tracts, entitled "Advice to Mothers," and describing the means for preventing ophthalmia neonatorum, etc., have been printed and distributed. Tracts have been collected from asylums for the blind also regarding the best means for educating and making useful this unfortunate class. At the Hygienic Congress, which is to meet this fall at Geneva, the subject will be taken up, and further measures adopted for carrying out the purposes of the society.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 14, 1882.

Dr. E. C. Seguin, President, in the Chair.

Dr. E. M. Cushier presented the heart and kidneys from a case of

MYXŒDEMA.

The patient was fifty-seven years of age, and the mother of twelve children. As near as could be ascertained, a change in the appearance or her face was noticed first about fifteen years ago, when it seemed swollen. Five years ago her face was distinctly swollen and presented a waxy appearance, and the lower extremities were also œdematous. The skin where it was tense was shining. The lips were thick and the eyelids baggy. There was a marked line of pallor between the eyelids and the cheek, and the skin of the cheek was brittle and dry. The tongue was unusually large, and increased in size toward the end of life. No cause for the œdema could be found. There were neither albumen nor casts in the urine; there was no evidence of cardiac disease, and the liver, spleen, and lungs were apparently normal. From this point the case went on, no specially new symptoms developing until about two weeks before death, when the patient had an attack of acute dermatitis, which at first was with difficulty differentiated from erysipelas. She also had acute inflammation of a portion of the left arm and a small circumscribed phlegmon in the right breast. Death occurred from progressive failure of heart power. There was slowness of intellectual action, slight diminution in hearing.

At the autopsy nothing special, macroscopically, was noticed concerning the spinal cord. The brain (as was to be regretted) could not be examined. The *heart* was enlarged, the aorta somewhat atheromatous, but the valves were sufficient. The *kidneys* were hard and there was atrophy of the cortical substance. The *liver* was of normal size and unusually firm in texture. All the *muscles* of the body were pallid. The thyroid gland had not been obtained. There was an enormous deposit of fat in the omentum, and there was infiltration throughout the cellular tissue, which seemed to be mucoid in character. The simple œdema of the extremities disappeared before death. The mucoid degeneration occurred only in the face, back, and upper part of the body.

Dr. Howe remarked that in some cases there was a large increase of subcutaneous fat as well as fatty tissue in other parts of the body, besides a chronic

general cellulitis which is progressive in character. Some authors had maintained that the œdema was the result of cellulitis.

Dr. Cushier said she supposed the œdema was due to the deposit of a low grade of tissue resembling mucoid tissue, and in some cases masses had been found, such as resembled the tissue of the umbilical cord, underlying the skin.

The President asked if the patient had numbness of any of the peripheral parts.

Dr. Cushier said there was no numbness. Mobility of the lips was absent, and there was a marked thickening or lack of sharpness of speech.

The President said he had been consulted recently by a patient upon whom he was almost ready to pronounce a diagnosis of myxœdema. The patient was a woman, forty-five years of age, who had unexplained œdema, which was peculiar, and produced a kind of leonine appearance of the face rather than a baggy look, with projection of the lips, marked thickening of the tongue, much impaired speech, and there had been œdema of the legs that had disappeared. She was anæmic. Examination of the blood showed 5,400,000 red corpuscles in a cubic centimetre, a good number, but ten per cent. of these were very small, many of them one-half, and a few not more than one-third the normal diameter, and the small globules were homogeneous and rounded.

The white globules were not abnormally increased in number. He thought the patient was not numerically anæmic, but was in the condition of microcythemia.

The mental processes were slow, memory was weak; she thought she was deaf somewhat, and she had had some numbness of the fingers.

The President regarded the connective-tissue diseases, apart from tumors, as an interesting part of pathology. For example, the hypertrophic condition, a disease of the connective tissue; the primary atrophy of connective tissue as shown in progressive facial atrophy; atrophy of large areas of connective tissue and connective-tissue substances, as bones, etc.

Some seven or eight years ago, before myxœdema had been recognized, he saw a case which he now regards as one belonging to this class. There was œdema of the face and extremities, not explained by any visceral condition nor fully by the anæmia.

Dr. Howe thought that the mucoid degeneration was secondary to a cellulitis.

CEREBRO-SPINAL MENINGITIS.

Dr. F. R. S. Drake presented a portion of the spinal cord removed from the body of a patient who gave the following history. He was a German, forty-five years of age, and a coalheaver by occupation, who was admitted to Bellevue Hospital on the 5th of June. On the 3d of June he was taken sick suddenly while in apparent health, and a few hours afterward had a convulsive movement, fell down, became unconscious, and remained in that condition until he died. He was admitted to Bellevue Hospital in a comatose condition, and there was considerable convulsive movement. After being placed in bed it was found that there was marked loss of sensation throughout the entire right side of the body. The temperature was 104° F.; pulse 98, hard, occasionally intermittent; the pupils were contracted, and respiration 24. Diagnosis of meningitis was made.

On the following day the temperature was 105° F.; pulse, 100; there was less loss of sensation, and the right side moved on irritation, although not so well as the left. There was considerable rigidity of the back, and tenderness upon pressure.

On the third day after admission he became partially conscious, but was unable to recollect distinctly. He was sufficiently conscious to protrude the tongue when told to do so. His temperature until the day before his death remained at about 105° F.; pulse, 120, and intermittent.

On the sixth day after admission the temperature was 106°; pulse, 150, and after a few hours the patient died.

At the autopsy all the organs were found normal except the brain and spinal cord. There was a large quantity of sero-purulent fluid at the base of the brain, and the entire surface of both hemispheres was covered with abundant purulent exudation. All the ventricles were widely distended with sero-purulent material. On removing the cord, purulent exudation was found throughout its entire length, but much the most marked upon the posterior surface.

The interesting features of the case were the suddenness and severity of the attack, and the restriction of the exudation almost completely to the posterior surface of the cord.

Dr. J. Lewis Smith said that cases of cerebro-spinal meningitis were not infrequent at the present time. He had seen a case within two weeks occurring in an infant who was taken suddenly with the disease, and after ten days the autopsy revealed lesions very much like those found in Dr. Drake's specimen. He thought it was the rule for the disease to commence abruptly.

Dr. R. W. Amidon presented a specimen of

SARCOMA OF THE BRAIN,

with the following history: The patient was a man forty-nine years of age, whose paternal grandfather died of cancer of the stomach, and his own sister died of cancer of the breast. The man had always had good health up to more than one year ago. There was no history of syphilis or injury of the head, and no coincident disease that would throw light upon his sickness.

In November, 1880, he had a severe attack of what was called neuralgia in the left occipital region, the seat of the most intense pain being between the mastoid process and the median line of the occiput, and extending down the back of the neck on the left side to the second and third cervical vertebræ. The pain was almost constant, with nocturnal exacerbations, and lasted about one month. The site of the pain was hyperæsthetic. This was nearly all the pain he had throughout the course of his sickness.

The next summer he was tolerably well, except a tired feeling in the legs considerable of the time, and occasional attacks of bad feeling which could only be ascribed to general malaise.

In October, 1881, his legs became quite stiff, particularly the right one, which was very anæmic and œdematous, and his walk was rather stiff and labored.

About this time he fell under the observation of two homœopathic physicians, one of whom diagnosticated locomotor ataxia, and the other anæmia of the spinal cord.

Dr. Seguin saw him about the middle of November, 1881, when he gave the history of having had, for the last three weeks, hemi-spasm, beginning in the right abdominal muscles, invading the leg and arm of the same side, but never involving the face. These spasms were unaccompanied by loss of con-

sciousness, but were confined to the right side. They recurred frequently, and finally he had a severe hemi-spasm which was attended by loss of consciousness, after which they occurred at short intervals. At that time Dr. Seguin made a note of hemi-paresis and stiffish walk of the right leg; pretty good grasp of the hand, no aphasia, choked disc, cardiac disease, or paralysis of the face.

About the only change in the symptoms which developed subsequently was an almost complete cessation of the spasms under the use of bromide and iodide of potassium in moderate doses.

On December 4th, when Dr. Amidon took charge of the case, there was some paralysis of the right leg and arm, the movements of the right arm and shoulder were restricted, speech was somewhat affected, but he had a very good grasp, no paralysis of the face or lesion of the optic nerve.

About the same time he had a severe attack of syncope, and on December 6th another fainting spell occurred, and he died. The symptoms immediately preceding death were complete right hemiplegia, almost complete aphasia, but no choked disc.

At the autopsy all the organs were found healthy except the brain. This presented a healthy appearance externally except that the convolutions on the left side were flattened, and also in the occipital region, whereas in the frontal region they were not at all flattened. There was no exudation or excess of fluid. In the brain was found a tumor situated in the paracentral lobule, and close to the main tumor was one of smaller size. Microscopical examination determined that it was a small-celled sarcoma surrounded by a zone of excessively vascular tissue. The peculiar features were 1st, retention of movement with considerable power in the periphery of one extremity, while at the same time the central power was paralyzed; 2d, the tumor was located where the centre for the foot and leg is, and it was so small and circumscribed that it afforded a good exemplification of localization of brain lesions.

Dr. J. Lewis Smith presented a specimen removed from the body of an infant that died at the age of fifteen days. Nothing unusual was observed with regard to the child; it was born at term, nursed well at first, and continued apparently healthy, when the first symptom noticed was rigidity of the masseters and inability to nurse. It was then discovered that it had

TRISMUS NEONATORUM

in its incipiency. At that time it was noticed also that the other muscles were somewhat stiff. The child was at once put upon the treatment which had been as effectual as any, namely, the use of hydrate of chloral in decided doses, and after four or five days the tonic rigidity of the muscles began to abate, and during the last twenty-four hours there was no rigidity, but rather a limp condition of the muscles of the limbs and neck. In the meantime, nourishment was administered by enemata. The child died on the fifteenth day. At the autopsy the only lesion discovered was

GENERAL PERITONITIS.

Dr. Smith remarked that there was no one anatomical lesion which caused the disease, and that its causes were various. The point of interest in this case was the existence of tonic spasms resulting from peritoneal inflammation.

The Society then went into executive session.

Correspondence.

FOREIGN BODY AROUND THE PENIS.

To the Editor of The Medical Record.

Sir: Cases of foreign bodies around the penis, like strings, silk ribbons, rings, etc., which boys while playing push over the gland or a part of the penis are not very seldom, but the case seen by me must be an unique one.

On July 13th a farmer boy, thirteen years old, was brought to my office for examination. The father stated that the boy complained of pain in the right side of the abdomen; the examination revealed considerable tenderness over the right hypochondriac region, no swelling, no redness. Diagnosis obscure: contusion or periostitis of rib. Ordered a liniment to be used and gave advice to bring the boy in again.

The next Monday, July 17th, the farmer came in a great hurry stating that he had found the source of the evil to be an iron nut which his boy had pushed over the penis.

His wife had noticed the same morning some blood in the bed, and he becoming frightened examined the boy all over, and found what is stated above; he was afraid that the whole penis was gangrenous. While going out in the country with him he told me that the boy had this nut on his penis since the week before the fourth of July, and that he remembers the day when the boy commenced to go lame; that the boy had worked sometimes in the field as long as he could stand it, and that this trouble was only accidentally found out by him. In consequence of the statement made by the man, I armed myself with a small anvil, chisel, iron saw, and hammer, to have on hand what might be necessary for an operation. Arriving at the farm I found, to my utter astonishment, an iron nut of large calibre around the penis, the weight and size of which I shall describe further on.

The iron nut was situated about one inch from the symphysis pubis, the penis and præputium in front enormously swollen in an S shape, looking bluish, and showing at several places small gangrenous spots. At the place of the ring there was a deep ulceration. The boy was laid on a table on his right side and chloroform administered, a small anvil put under his penis, and while I was holding the nut to prevent it from slipping off the anvil, I directed the farmer to use the chisel and split the nut with renewed strokes of the hammer; after splitting it we used the round handle of the chisel as a wedge, and by hammering on it we were able to break the nut in two parts. To my great surprise I found another ring behind this nut, which I believed to be a leather washer, but which proved to be an iron washer. The same process had to be gone through with chisel and hammer, but it was very difficult to get this ring open, as it would bend instead of break, but after half an hour's effort I was enabled to open it so far as to liberate the ulcerated part of the penis out of the ring. The whole operation lasted three-quarters of an hour, during which time I kept the boy in good narcosis.

At the place where the two rings laid the skin was entirely cut through to a distance of about one inch, the edges of the skin retracted and undermined, the corpora cavernosa denuded, but the

urethra intact; the boy had been able to urinate all the time.

The wound was washed with carbolized water, and lint put on with carbolized oil. The wound is granulating nicely and will be healed in a short time. The size of the nut is 1¾ inch square, the thickness $\frac{1}{16}$ inch, the diameter of the internal ring or winding ¾ inch, the weight is 4½ ounces and 20 grains. The size of the ring was correspondent to the winding of the nut, the thickness ⅛ of an inch, and the weight 6½ drachms, which makes 5 ounces, 2 drachms, and 50 grains altogether. The boy must have suffered intense pain by the continual tearing of these two foreign bodies on the ulcerated part, and only shame or fear of punishment would prevent him from telling the truth to his parents. In looking over my library I found a similar case narrated in Billroth and Pitha's large work on "Surgery," vol. iii., second division, part 8, page 27. In this case a ten-year-old boy had an iron nut weighing 50 grains around his penis for two years. The penis was found hard and swollen, bluish, the skin destroyed, corpora cavernosa and urethra denuded. The nut had to be held by two assistants with hand vises, sawed through with an iron saw, and removed by chisel and wedges.

As this case appears to be a very unique one, I thought it worthy of being published, and, incredible as it seems, the whole narration is nothing but the truth.

GEO. SEILER, M.D.

ALMA, WISCONSIN.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 6, 1882, to August 12, 1882.

PROMOTIONS.

COLONEL CHARLES H. CRANE, Assistant Surgeon-General, promoted Surgeon-General, with the rank of Brigadier-General, to date from July 3, 1882, vice Barnes, retired.

LIEUTENANT-COLONEL CHARLES C. KEENEY, Surgeon, to be Surgeon, with the rank of Colonel, June 30, 1882, vice Cuyler, retired.

LIEUTENANT-COLONEL JOHN F. HEAD, Surgeon, to be Surgeon, with the rank of Colonel, June 30, 1882, vice King, retired.

MAJOR JOSEPH B. BROWN, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, vice Simons, retired.

MAJOR DAVID L. MAGRUDER, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, vice Keeney, promoted.

MAJOR CHARLES PAGE, Surgeon, to be Surgeon, with the rank of Lieutenant-Colonel, June 30, 1882, vice Head, promoted.

CAPTAIN JOHN BROOKE, Assistant Surgeon, to be Surgeon, with the rank of Major, March 2, 1882, vice Frantz, deceased.

CAPTAIN WILLIAM H. GARDNER, Assistant Surgeon, to be Surgeon, with the rank of Major, June 23, 1882, vice Norton, deceased.

CAPTAIN CHARLES SMART, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, vice Brown, promoted.

CAPTAIN WILLIAM S. TREMAINE, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, vice Magruder, promoted.

CAPTAIN MORSE K. TAYLOR, Assistant Surgeon, to be Surgeon, with the rank of Major, June 30, 1882, vice Page, promoted.

HARTSUFF, ALBERT, Major and Surgeon. Having reported at these Headquarters on 3d instant, surrendering unexpired portion of his leave of absence, will proceed to Fort Union, N. M., and report to the commanding officer for duty. S. O. 153, Department of the Missouri, August 4, 1882.

TILTON, H. R., Major and Surgeon. Granted leave of absence for fifteen days. S. O. 155, Department of the Missouri, August 7, 1882.

TURRILL, H. S., Capt. and Asst. Surgeon. Granted leave of absence for ten days. S. O. 139, Department of the East, August 10, 1882.

VOICE PRODUCTION.—Dr. P. H. Cronin, of St. Louis, Mo., writes: "In your issue of July 22d I was pleased to note a brief review of Patton's 'Voice Production,' and that the 'Singing Voice' would form the subject of an essay at the next meeting of the American Laryngological Association.

"It is a fact well known to those of us who have made the study of voice production an earnest one that far too little attention is paid by the mass of the profession to acoustic physiology as affecting vocal quality. As to the hundreds of cases of broken-down singing and speaking voices that claim the physician's attention, only a leading specialist here and there is competent to treat them.

"There is no good reason why every practitioner should not be able to give intelligent advice in such cases, which with every year become more numerous. Music is becoming a power in every home, and on all sides singing societies and concert organizations are springing up, with constantly widening influence. Elocution is being largely cultivated by another class of persons, outside of schools and colleges, and the miserably cultivated voices of nine-tenths of our so-called pulpit orators give evidence of faulty voice production.

"It may be that this want of knowledge in regard to vocal troubles is the result of that same education which, not many years ago, taught physicians to slight the practice of obstetrics and leave the field to old women. Happily, this stupidity has been replaced by a genuine interest in midwifery, which has placed that specialty in the front rank of the profession. But the troubles of the singing and speaking voice are as a *terra incognita* to doctors in general, while the real *practice* is left to men and women outside the medical profession.

"In 1878 my State sent me as commissioner to the Paris Exposition, and being a lover of music as well as of medicine, I determined on devoting a few leisure hours to the enjoyment of the former as a relief from study of the latter. I made visits to London, Dublin, Geneva, and Rome, and in all those capitals, as well as in Paris, I noted not only impairment of voice, but a letting down of physical energy in hundreds of cases of those studying singing. This was especially the case among the female singers. In a conversation with Dr. Thos. Hayden, of Dublin, a gentleman well known to the profession, I learned that the practice of singing, as taught by some of the so-called 'methods,' was seriously affecting young women; indeed, he surprised me by saying that 'Music killed more women than medicine.'

"Returning to America, I gave the subject of the singing voice and its dangers quite extensive study, and last year gave some of my ideas on the matter to one of our local journals. This brought down on me the fire of enraged 'voice builders,' and the discussion reached to nearly every point in the Mississippi Valley.

"The 'learned' physician will probably smile at the idea of the singing voice claiming the serious attention of a leading specialty and of a congress of doctors. Yet had Manuel Garcia not made his discovery of vocal action while viewing himself in the mirrored surface of the river Serpentine, those doctors would probably be little advanced in their specialty. For to a *singer* they owe a great part of what is known of the vocal apparatus. Flint copies Garcia's ideas *in extenso*, and characterizes the man himself as 'one profoundly versed, theoretically and practically, in the knowledge of music, and possessed of great control over the vocal organs.'

"Mr. Patton's work, though faulty in some respects, is creditable to the author's good sense, inasmuch as he quotes only recognized medical opinions. There seems even here, however, a slight misunderstanding of regional anatomy, for on page 11 he confounds 'clavicular' breathing with the 'abdominal' type so severely condemned by Dr. Wing, of Boston. Aristotle says: 'Define your terms and discussions will cease.' Abdominal breathing of the exaggerated kind has an analogue in emesis or defecation. The descent of the diaphragm displaces the abdominal viscera, and we can easily see what would be the result in cases where young girls are practising this modern 'method.' So great is the excess to which this *abominable* method is carried, that the son of ex-Mayor Cole, of this city, tells me pupils are *finished*, when by a powerful action of the abdominal muscles, a *piano can be moved*, and this in Boston, too.

"The reference to Madame Mara's voice, as showing the microscopic grades of tension of the vocal cords, is merely the propagating of a long-accepted theory that the vocal cords alone give graduation and tone. That Dr. Cohen accepted this theory is not to be wondered at. Helmholz, in his enthusiastic forgetfulness of Deity, tells us that were an optician to bring him such a faultily constructed instrument as the human eye he would reject it. But the great scientist forgot that an element known to us as *vitality* enters into the working of the human eye, and makes it more than a match for any scientific substitute. Dr. Cohen, in like manner, forgets that the vocal cords play but a small part in the rising and lowering of the pitch, the resonating chambers, with the partial tones and the shortening of the vocal tube, doing the major part of the work. In fact, the 'seventeen thousandths of an inch shortening' of a vocal cord would not in its resultant tone be perceptible to any but *heavenly ears*.

"Far from any apology being necessary for the appearance of a notice of such a work as Mr. Patton's, I feel that such notices are productive of good. Doctors are, after all, but units in the social aggregation of humanity, and being *men* as well as doctors, are impressed by surrounding influences. Hence, by a reflex action the needs of society, its culture and progress, should find sympathy and aid amongst those who, by reason of their educational training, should be above the mass of humanity."

COMPETITIVE EXAMINATION FOR THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY.—The following is a list of candidates for the position of Assistant Surgeon, United States Army, in the order of merit: W. E. Hopkins, University of New York and University of Virginia; C. C. Barrows, University of Virginia, Va.; Benj. Munday, Medical College of Virginia, Va.; W. L. Kneedler, Jefferson Medical College, Pa.; G. F. Wilson, University of Virginia, Va.; W. O. Owen, University of Virginia, Va.; P. R. Egan, College of Physicians and Surgeons of New York; W. J. Wakeman, Yale Medical College, Conn.; Edward Everts, University of the Pacific, Cal.; C. N. B. Macauley, Jefferson Medical College, Pa.

THE BIRTH OF AN ELEPHANT.—Dr. Gustavus E. Sussdorff, of New York, contributes to the July number of the *New York Medical Journal and Obstetrical Review* an account of the process of parturition as it took place in the case of the elephant "Queen" last February. The period of gestation was 597 days. There was no noticeable enlargement of the abdomen until it suddenly became quite prominent the day before labor began. This enlargement did not subside with the expulsion of the fœtus and after-birth, but continued four days longer. During the latter month the mammæ became swollen, and soon filled with serous milk. These were the only signs of pregnancy to be seen. The labor began at 3 P.M., February 2d. At this time the mammæ were greatly distended with milk, which came away continuously in drops. The vagina now began to drop down and swell. In a short time thick mucus began to come from the vagina in long ropy strings, and almost poured out just before delivery. From 3 until 8 o'clock "Queen" was evidently uneasy, as she constantly moved her body from side to side, but did not seem to suffer *pain*, and quietly munched some hay up to the very moment of delivery. At 8.10 the young elephant was born, the head presenting, completely enveloped by the unbroken membranes. The head and part of the body rested between the hind legs of the mother, and touched the ground. Without waiting a moment, the mother ruptured the membranes with her two hind feet, when the young one rolled out on its back. The membranes were no sooner liberated than they quickly returned into the vagina. The umbilical cord had not been seen at all, having probably been torn away during the descent of the fœtus. The mother now quickly turned to the young, and on seeing it began to roar and bellow furiously, which she continued for ten minutes. As soon as she saw the baby she also at once placed one fore-foot on it and rolled it several times, as one does a lemon under the palm of the hand, the bellowing and roaring

continuing. In a moment or two more she placed her abdomen upon a short post in the ground, to which she was chained, standing almost upon her head, and grasping the post with her trunk, thus forcing the abdomen with great power against the post. "Queen" remained in that position for about ten minutes; then became quiet, and, while playing with her young, took some food. Nothing indicative of after-pains could be recognized after this, and in one hour and thirty minutes the placenta was expelled. With it there came about two quarts of clotted blood. There was no hemorrhage either from the uterus or from the umbilicus of the calf. The duration of labor was five hours and ten minutes. The calf, a female, weighed 245 pounds, and stood just three feet high. It began nursing one hour and forty minutes after birth. It had two middle upper teeth. The umbilical cord entered the abdomen about three inches anterior to the vagina, and had been detached very close to the abdomen, as none was visible at that point, the canal being open and large enough to admit a good sized finger for half an inch. Dr. Sussdorff remarks that there are several very interesting and instructive points in this history. First, the period of gestation is evidently not affected by change of climate and captivity, lasting about nineteen and a half months. The time of labor is short, and evidently there is not much pain. The sagacity of the animal is remarkable, as shown by the manner in which she ruptured the membranes, the means she took to excite respiration by rolling the young, and, finally, her effort to express the placenta from the uterus. He then describes the placenta and the fœtal membranes, comparing them with those described by Owen, and adds a summary of various observations that have been made of the milk of the elephant as compared with that of other animals, giving drawings which show its microscopical characters in comparison with those of cow's milk.

A Jamaican Galactogogue.—Nursing Jamaican women are in the habit of drinking an infusion known as cotton-leaf tea, in order to increase the secretion of milk. Mr. Anderson has employed this in women whose milk was scarce, and was convinced of its powers as a galactogogue. The infusion is made from the leaves of the plant known as the *gossypium bortadense*. The dose is six or eight leaves to the cup, and according to the effects obtained four cupfuls or more may be taken in twenty-four hours; some are in the habit of drinking two or three litres of the infusion daily. Its taste is not disagreeable, and many take it as they would black tea.—*El Sentido Cat.*

Abscess of the Brain following Fracture of the Skull.—Dr. J. H. Shorter, of New York, communicates the following interesting case: Jenny I——, aged three years, of good personal and family history, was first seen on July 9th. On July 6th she had slipped, and, falling forward, had struck on a piece of kindling wood which she held in her hand. She did not seem stunned much by the blow, which was inflicted just below the superior edge of the left orbit. There was no apparent injury of the globe, and only a contused wound of the upper lid, with but slight abrasion. Such was the report of the parents, who insisted that the piece of wood, which had blunt, square ends, did not penetrate the skin at all. On July 9th there was œdema and puffing of the upper lid, and some exophthalmus; the child seemed to suffer from pain. The parents would consent to no operative procedures whatever. On the 11th the local symptoms were worse and constitutional disturbances very well marked. From a state of lassitude the patient gradually fell into a stupor. On the 12th, the little one being in the condition mentioned, a deep incision was made immediately below the upper edge of the orbit, and a large amount of pus evacuated. Marked amelioration of the symptoms followed. On examination with the finger passed through the external opening, a fracture of the orbital plate of the frontal bone was discovered, of rectangular shape, 25 by 12 mm. in size. The fragment of bone seemed to be driven upward, and the diagnosis of meningeal and probably cerebral laceration also was made. Two days later the temporary improvement of the symptoms was succeeded by a relapse. Dr. Sabine, aided by Drs. Gruening and Oppenheimer, then removed with great difficulty a piece of bone which was tilted upward perpendicularly into the brain substance. Subsequent syringing of the cavity of the wound with a one per cent. solution of carbolic acid caused immediate improvement, restoring consciousness and reducing temperature from 105° to 102½°. The symptoms remained fair till the 14th day, when spasmodic jerking of the left shoulder set in; later there was diaphragmatic spasm, much restlessness and groaning. On the 16th day the temperature was found to be much lower on the right side than on the left (102⅘° and 104⅕° respectively). This difference remained to the last. Abscess of the brain being determined upon as the probable cause of the continued bad symptoms, Dr. Shorter passed a trocar up almost perpendicular into the anterior lobe of the cerebrum through the opening of the fracture. Some serum but no pus escaped; no improvement was apparent. Patient died the next evening.

The autopsy revealed a general meningitis, and on dissection an abscess cavity the size and shape of a pigeon's egg, occupying the anterior part of the left hemisphere, but not communicating with the wound in the orbital plate or the surface of the brain. The trocar had passed within a millimetre of the abscess and entered the ventricle. A piece of bone similar to but smaller than that removed was found attached to the opening and projecting upward into the brain. The case is of interest as showing that injury may occur to this thin bone, and consequently to the brain substance, without perforation of the skin or soft tissues. It also shows the importance of the early removal of collections of pus around the orbital cavity.

Another Sign of Death.—*La Electricidad* announces a discovery which will prevent the horrible consequences of precipitate burials. The electric current affords a certain method of determining whether life is really extinct. Two or three hours after arrest of the cardiac beat the entire muscular system has lost its excitability. An electric current then passed through the muscles fails to call forth any contraction. If this procedure be adopted five or six hours after cessation of the signs of life, and no contraction is produced, death is certain, since neither fainting nor catalepsy can abrogate muscular contractility.

A Healthy Brain Necessary to a Free Will is the title of an interesting discourse delivered by Dr. C. G. Comegys at the banquet given by the medical profession of Cincinnati to the Association of Medical Superintendents of Insane Asylums.

HEMORRHOIDAL DISEASES.

Equitation Considered as a Cause, Preventive, and Cure.

By WILLIAM BODENHAMER, A.M., M.D.,
NEW YORK.

The charming exercise, *horseback-riding*, was highly extolled, both by the ancient and the modern physicians, not only as a source of convenience and pleasure, but also as a most valuable remedy in the treatment of some diseases. Hippocrates himself speaks approvingly of the practice of horseback riding at full gallop, in the open fields, as a remedy for some affections ("De Victus Ratione," lib. ii.). Oribasius, who relied so much upon other gymnastic exercises as remedial measures in the treatment of disease, passes the highest encomium upon equitation. After declaring that riding slowly is tiresome, he goes on to say that when a horse is put on the stretch, though he violently shakes the whole body, yet this concussion is beneficial, for it strengthens the entire system, especially the stomach; and it purges and quickens the organs of sense, beyond all other exercises ("Collectorum Medicinalium," lib. vi., cap. 24, "Equitatione." Folio. Basilæ, 1557). The Latin writers, as well as the Greek, also allude to horseback-riding as a therapeutic measure in the treatment of disease. The Romans, however, although they exceeded the Greeks in their admiration and prosecution of gymnastic exercises generally, fell greatly behind the Greeks in their attention to and recommendation of horseback-riding as a remedial measure. The celebrated Bagliva, however, was one of its greatest admirers, and speaks of having cured two hypochondriacal patients, who were desperately ill, by causing them to ride in the country on asses ("Specimen de Fibrâ Motrice," lib. i., cap. 8. In Opera Omnia. Medico Practica et Anatomica. 8vo. Lugduni, 1710). As an evidence that the Italians, excepting the military, were at an early period not very much addicted to horsemanship, especially to fast riding, I will quote a proverb of theirs, which says "*A galloping horse is an open sepulchre.*" In consequence, therefore, of this established principle, or opinion as it were, of theirs, they conducted their races at Florence by running the horses without riders upon them. And as a further evidence of the timidity of the Romans, which kept them in those days from the enjoyment and benefit of the best and most useful kind of riding, I will refer to some of the sayings of Martial, one of their celebrated poets, who advises his friend Priscus, in hunting the hare, to moderate the speed of his horse; and finally warns all hunters of that animal to beware of fast riding, lest they break their necks, instead of killing the hare ("Epigrammatum Medicæ aut Philosophicæ," lib. xii., Epig. 14. 4to. Venetiis, 1657). Mr. Fuller says: "The exercise of horseback-riding, upon several accounts, may be esteemed the best and noblest of all exercises for a sick person; whether we consider it with respect to the body or the mind. If we inquire after what manner it affects the body, we shall find that it is a kind of mixed exercise, partly active and partly passive. The lower parts of the body being in some measure employed, while the upper parts are almost wholly remiss or relaxed. Nay, where a man is easy, is sure of his horse, and rides loose, there is very little action on his part; but he may give himself to be as careless almost as if he were seated on a moving chair, so that he may be said to be exercised rather than to exercise himself, which makes the case widely different from almost all other sorts of exercise, as walking, running, stooping, or the like; all of which require some labor, and consequently more strength for their performance" ("Medicina Gymnastica," p. 140. 8vo. London, 1740).

I would observe here, by way of digression, that anciently, at different periods, and for a longer or shorter time, horses were managed by the voice alone, or by the switch, without either bridle, saddle or stirrups. For saddles they sometimes used the skins of animals, or cloth. Even the aborigines of our own country not long since, rode and managed their horses somewhat in the same manner, if some of them do not even now do it. Saddles when first made, were without pommels; and the ladies are especially indebted to the celebrated Catherine de Medici for the introduction of the pommel on their saddles. Previous to her time, female equitation was conducted *à la planchette.* According to the distinguised Abbé Brantôme, Catherine de Medici was the most perfect and accomplished horsewoman of the age in which she lived, and he says that she introduced the pommel on the lady's saddle for the better display of her unequalled symmetry of person.

Equitation is a passive-active exercise, and differs materially as to whether the horseman rides according to the French or the English fashion, so distinguished. The French rider, with long stirrups and only the ball of the foot resting in them, sits firmly in the saddle with his nates and the saddle in close and constant contact, as if he were part of the horse himself; by which it will be observed, the whole pelvis is the principal *point d'appui*, so that the motions of the horse are imparted to the trunk, and the shocks and vibrations occasioned by them, act more forcibly upon the abdominal viscera. The muscles that are principally engaged in this active movement are those of the trunk and inner sides of the thighs. While, on the contrary, the English rider with short stirrups, and the instep of the foot resting in them, does not sit closely and firmly in the saddle, but makes the stirrups serve him as *points d'appui*, in consequence of which his body is therefore raised at every movement of the horse, because the nates are unsupported, and by reason of this he is constantly compelled to exert himself in more active movements in order to maintain his upright position. It is true he may have the advantage, if it really is an advantage, of more effectually opposing the shocks occasioned by the motion of the horse, and longer warding off the fatigue which they induce; but are not these very efforts which he is continually compelled to make to keep his erect position, almost, if not equally tiresome. These two methods of riding, then, doubtless have their advantages and disadvantages, as remedial measures, and must be made to conform to the exigencies of the patient's condition. For the prevention and the cure of the hemorrhoidal disease, however, the French fashion of riding is, as a general rule, for obvious reasons, the best.

After having in the preceding general remarks referred to the subject of equitation as a remedy in diseases generally, I will now proceed to consider it especially in relation to the hemorrhoidal disease.

It was an opinion held both by the ancients and

moderns, that horseback-riding, though valuable as a remedy in some diseases, yet it always and under all circumstances, tended to the production of the hemorrhoidal disease, and that it was especially prejudicial to those already suffering from it. This opinion or supposition, even now entertained by so many, can only, however, be accepted as true to a very limited extent. Such an opinion I have always considered pernicious, inasmuch as it deters many persons of sedentary habits, invalids and others, from availing themselves of this delightful and sanative exercise. It is true that violent horse exercise may prove a cause of hemorrhoids in consequence of the irritation and chafing which it occasions in the ano-perineal region in those who are unaccustomed to horseback riding, or those who ride for the first time, or ride a long distance in warm weather, which in such produce contusions and chafings, which more or less tend to the production of hemorrhoids. And I will here further remark that riding without a saddle, that is, bareback, would also be well calculated to cause or to lay the foundation of the hemorrhoidal disease. This effect, however, would not be due to the concussions produced by the motion of the horse, but solely by the heat given off and received from the animal in a long ride, especially in warm weather, and by the contusions and chafing of the anal region which attend this kind of equitation. The ancient Romans seemed to have been aware that horseback-riding without a saddle would cause hemorrhoids, for Martial in his epigram entitled "Ephippium" advises the coursers on this account not to ride bareback;

> "Strangula succincti venator sume veredi;
> Nam solet à nudo surgere ficus equo"
> (*Op. Cit., lib. xiv., Epig.* 86).

Horseback-riding must therefore be taken with precaution and prudence on a good horse and on a good saddle by those who are acquainted with the science and art of horsemanship, and accustomed to riding. If these prerequisites obtain, equitation is much more frequently a prevention or a cure of hemorrhoids than a cause of them. I am well aware, however, that it under all circumstances is considered a potent cause of hemorrhoids by a large number of eminent authorities. I must be excused, however, from naming but two or three of the old authors. The celebrated Truka maintained that horseback-riding is uniformly a cause of the hemorrhoidal disease ("Historia Hæmorrhoïdum." 8vo. Vindobonnæ, 1794). Baldinger says that he has seen the horsemen in the army much more frequently affected with hemorrhoids than the foot soldiers were ("Introductio in Notitiam Scriptorum Medicinæ Militaris." 8vo. Berolini, 1764). Gabelschower reports the case of an old man, who, at the time of a profuse hemorrhoidal bleeding, took a long ride on horseback, which completely suppressed the hemorrhage, but a hematuria soon followed of which he died on the eleventh day ("Curationum et Observationum Medicinalium," cent. vi., cur. 50, p. 116. 12mo. Tubingæ, 1627). This case, which was intended to prove that horseback-riding is exceedingly dangerous in hemorrhoids, signally fails, in my opinion, to do so; and to say the least of it, it is of a very equivocal character.

Now, on the contrary, however, the illustrious Baron Larrey, who was so long Surgeon-in-Chief of the Imperial Grand Army of France, under the Great Napoleon, in accordance with his vast experience, declared positively that the motion of the horse was much better calculated to cure hemorrhoids, than to cause them; that he had even seen soldiers, on the eve of an engagement, and in the midst of a violent attack of hemorrhoids, compelled to mount their horses and remain in the saddle for hours, and who, through the excitement of battle, entirely forgot their infirmity and found themselves cured when the conflict was over. Indeed, he himself was in the habit of causing soldiers affected with hemorrhoids, to ride on horseback at full gallop; and he declares that he never saw any bad effects to supervene, but generally, on the contrary, the most salutary consequences ("Mémoires de Chirurgie Militaire, et Compagne." 8vo. Paris, 1817). The able and the distinguished M. de Montègne says that, "I do not know of a surer, or a better preservative from hemorrhoids than habitual equitation" ("Des Hémorrhoïdes, ou Traité Analytique de toutes les Affections Hémorrhoïdales, p. 106, 8vo. Paris, 1830). Being well acquainted with General H. H. Sibley, a Creole of the State of Louisiana, now residing at Fredericksburg, Virginia; and knowing that he had been a commanding officer in the cavalry service for the greater part of his life, I wrote him on the subject of equitation, as a cause, a preventive, and a cure of hemorrhoids, and asked him to give me his experience and opinion in relation to it. The following is an extract from his letter, dated June 4, 1882: "In regard to your inquiry relative to equitation, as a *cause*, preventive, and cure of hemorrhoids, I can speak ex cathedrâ. I entered the cavalry of the United States Army in 1838, and served throughout every climate on this continent, up to 1861. Again in the Confederate Army, during the continuance of that war; and lastly in Egypt as a general officer for four years. During this period of over thirty years' almost continual service, from the tropics of Mexico to the frozen crests of the Rocky Mountains, I have never been afflicted with any disorder of the anus, nor have I ever known a soldier in the ranks thus afflicted. True, they were and needs must be entirely free from any malady on their enlistment; but surely horseback exercise never *occasioned* any malady of the anus. Amongst the officers, but two in my regiment were thus afflicted; one a captain, who complained of some anal malady, but who never shirked the saddle; another who had chronic piles and who always shirked duty. He is still a living monument of worthlessness, though fully seventy-five years old. Thus you will perceive that my experience proves that horseback-riding rather *prevents* than induces piles. Whether it tends to alleviate or to cure them I have no knowledge or experience, never having been afflicted in this way myself; nor have I ever heard of a complaint from soldiers. I think the constant exercise, together with the regular habits and *initial* healthy condition of the cavalry soldier preserves the healthfulness of the anal parts. It was my constant habit after a long march in the saddle, to bathe the parts in a basin or in the creek, and the soldiers generally followed my example."

I have myself witnessed the good effects of horseback exercise, in several instances. Some of the patients had the disease in the form of varices in the anal region; while in others it was attended by regular organized tumors. These patients positively refused surgical treatment, and were then advised to lay aside the numerous pile nostrums they were using, and try regular horse-exercise for a while, which they did. The pressure of the saddle and the motion of the horse in these cases ap-

peared to exert a most salutary influence in removing the congestion and the tumors. Indeed, the agitation of the intestines, and the repeated concussions occasioned by the motion of the horse, favor the free circulation of the blood through the entire abdominal cavity, and especially through the hemorrhoidal vessels, and at the same time, the inferior portion of the rectum, with all the other contiguous parts, which participate in this healthful movement, receive an augmentation of tone and elasticity which are well calculated to prevent and to dissipate engorgements; and furthermore, there is scarcely anything that can assist, in a more efficacious manner, the action of a torpid liver, than the gentle shaking motion of horseback-riding, which induces a more active secretion in this organ, and absorption in the intestines, by accelerating the circulation. I have known many planters, as well as overseers of plantations, in the extreme southern portion of our country, some of whom were of full habit and free livers, who appeared to be nearly half their time on horseback, and yet, as it were, knew nothing of the disease, never having experienced an attack of hemorrhoids.

In my opinion horse-exercise is not prejudicial, even to the hemorrhoidarian, but on the contrary, is just the reverse. There is not a more certain preservative from hemorrhoids, than regular horseback-riding. Should the patient, however, be unaccustomed to equitation, and take it in a sudden and violent manner, he will suffer severely for several hours, especially if he has external tumors, or internal ones, in the least protruded. I would, therefore, advise such a patient not to take this exercise if he has inflamed external hemorrhoids, or internal ones protruded, but first have the inflammation subdued and the tumors completely returned, before mounting the horse. It is true, that in such cases it is frequently inconvenient and a little painful at first to ride, yet, if persevered in, great and lasting relief will often be obtained; and I do not think that hemorrhoidal tumors, whether external or internal, should ever contra-indicate, at least a trial of horse-exercise, by those especially who are averse to all surgical treatment; for if equitation is taken in a proper manner, carefully and prudently, it is a powerful means of preventing and of curing this affection.

I would remark in conclusion, that the gymnastic movement-cure of hemorrhoids, which has some advocates, is founded somewhat upon the same principle as that of equitation; but, while it is much more accessible to the majority of patients, it nevertheless falls far short of being as efficacious as horse-exercise.

A gymnastic movement for the cure of hemorrhoids, it is said, is practised at Bellevue Hospital, with success. "It consists simply in trying to touch the toes with the fingers, without bending the knees. This movement, though difficult at first, soon becomes easy; it not only strengthens and develops the muscles of the abdomen, but also those of the legs and thighs. It assists the action of certain remedies, and thus aids in the cure" (New York Medical Record, September 27, 1877, p. 599).

249 Madison Avenue, New York.

Sir J. Lubbock (*Journal of Linnean Society*) concludes, from a prolonged and careful series of experiments, that bees distinguish colors, and have a decided preference for blue.

INJECTIONS OF THE VIRUS OF HYDROPHOBIA INTO THE CIRCULATION

Do not Produce Rabies and Seem to Confer Immunity from the Disease.

Translated from the French by GEO. M. STERNBERG,
Surgeon, U.S.A.[1]

[*Note by translator.*—Not having seen in the medical journals any reference to the following important and interesting communication to the French Academy, I have thought it worth while to translate it without abridgment for the benefit of the readers of The Medical Record.]

Since I have undertaken to study hydrophobia I have had occasion a number of times to inject the virus of rabies into the jugular vein of the sheep, and I have never seen the disease appear as the result of such injections. Moreover, animals which have been inoculated in this manner, having been subsequently utilized for other experiments and having been inoculated with the virus of rabies in other ways have not contracted hydrophobia. The following are the principal facts which I find recorded in my record of experiments:

Experiment No. 1.—May 4, 1879.—Inoculated two sheep, one in the jugular vein, and one in the subcutaneous connective tissue; the last became rabid on the 10th of June, and died two days after; the other resisted and was again inoculated by a different method on the 9th of October and on the 23d of December, without result. This sheep was utilized for other researches March 11, 1880.

Experiment No. 2.—October 9, 1879.—Three sheep were inoculated with the virus of rabies, *two by punctures* and scarifications and one by *intra-venous injection;* the two first died of hydrophobia on the 26th of October and the 7th of November. The other was re-inoculated by punctures and scarification March 26, July 8, and December 19, 1880, without having contracted the disease.

Experiment No. 3.—December 19, 1879.—Two sheep were inoculated with the saliva of rabies, one by hypodermic injection, the other by *intra-venous injection.* The first died of rabies January 24, 1880; the other in good health on the 24th of February, was re-inoculated by different methods on three different occasions without result up to the time it was employed for other researches, December 9, 1880, two months after the last inoculation.

Experiment No. 4.—December 31, 1879.—Two rabbits were inoculated by punctures, and two sheep by *intra-venous injection.* The two rabbits died of hydrophobia January 17 and 22, 1880. The two sheep were re-inoculated by scarification March 20, May 14, and July 18, 1880, but still remained in perfect health on the 9th of December of the same year.

Experiment No. 5.—April 19, 1880.—Two rabbits were inoculated by punctures, and one sheep by *intra-venous injection.* The two rabbits died of hydrophobia April 30th and May 9th. The sheep was re-inoculated by punctures and hypodermic injection June 24th and October 17th. This animal was utilized for other researches January 25, 1881.

Experiment No. 6.—February 3, 1881.—Two sheep inoculated with virus of rabies, one by hypodermic injection, the other by *intra-venous injection.* The first died of hydrophobia March 2d, the other

[1] Communication to the French Academy of Sciences by M. V. Galtier, presented by M. Bouley (C. R. Ac. des Sci., t. xciii., pp. 284-5).

resisted and was re-inoculated by punctures and scarification March 13th and 17th. It remained in good health July 28th.

Experiment No. 7.—March 13, 1881.—One goat and three sheep were inoculated. One of the sheep, inoculated by punctures, died of rabies April 22d. The two other sheep and the goat, inoculated by *intra-venous injection*, were re-inoculated by scarification March 27th and July 28th, without result.

Experiment No. 8.—February 19, 1881.—Five rabbits received, as a drink, a mixture of water and saliva of rabies. Three resisted and two died of hydrophobia March 2d and March 9th.

The following conclusions are drawn from these facts:

First.—Injections of the virus of rabies into the veins of the sheep do not induce rabies, and seem to confer an immunity against it.

Second.—Rabies may be transmitted by injection of the virus, although the locality where the inoculation takes place in this case has not yet been determined. It is nevertheless demonstrated that there is danger of contracting the malady by the introduction of the virus into the alimentary canal.

I propose to verify the fact of immunity as the result of intra-venous injections by experiments upon *the dog*, and I am endeavoring to ascertain if intravenous injection of the virus *practiced a day or two after a bite, or an inoculation with virus, can preserve an animal from rabies.*

A PECULIAR CASE OF TRACHOMA.

By FRANCIS VALK, M.D.,

ASSISTANT SURGEON MANHATTAN EYE AND EAR HOSPITAL, VISITING PHYSICIAN TO RANDALL'S ISLAND.

Granular lids, as illustrated at the clinics, generally present the same picture, with more or less superficial ulceration and vascularization of the cornea, from contact of these trachomatous bodies when the eyes are opened and shut. The treatment is always about the same, while the results are only a relief to the patient without a cure. As a change from the usual run of these cases, the following one may be at least interesting, and perhaps instructive, to others, both in its appearance and treatment.

Frank W——, aged five years, of Beaufort, South Carolina, was sent to me by Dr. Cooper for advice and treatment, on September 8, 1881, with the following history from his mother: When the boy was born the eyes seemed to be all right, until six months of age, when they noticed some small superficial abscesses on the right upper lid; these were lanced, and a day or two after there was a slight discharge of matter from both eyes, small in quantity and gluing the lids together at night. This condition was treated by some mild astringents, until two years ago, when both lids became inflamed, with an increased discharge of pus. Again applications were applied, but with no improvement, nor were the lids even inverted nor their correct condition ascertained until about one year ago, when the present condition was discovered, but still only treated by the daily instillation of sulphate of copper.

I found the boy very anæmic. Strumous diathesis, appetite poor, and bowels irregular. Has slight naso-pharyngeal catarrh, with enlargement of both tonsils. Family history good, and surroundings, when at home, excellent. He opens the eyes well, no photophobia or lachrymation, and both cornea perfectly clear and bright; has slight blepharitis and refraction hyperopic, by the ophthalmoscope.

On examination of the lids, the lower presents the usual appearance of chronic conjunctivitis, smooth, and somewhat congested; on everting the upper lids, I found them to be covered with perfectly *dry* bodies, a very pale pink in color, no signs of blood-vessels in any part of the everted lids; they were hard to the touch like cartilage, and shaped like little squares lying close together, about 1 mm. on each side, with a deep and narrow sulcus between them, and small masses of dry pus lying in the retrotarsal fold, the presenting surfaces of these trachomatous bodies were perfectly flat and even.

The treatment adopted was first directed to his general health, while locally I applied a strong solution of nitrate of silver, any excess being removed by absorbent cotton. After two or three weeks' treatment, without any improvement except in his general health, he was seen by Prof. D. B St. John Roosa, of the New York University. He advised me to try scarification of these bodies with a sharp needle and to continue the silver, should this fail, to then try some operative interference. Following his advice the lids were freely scarified, with only slight hemorrhage, and the applications continued. Finding no material improvement, I decided to operate, and with the assistance of Drs. H. C. Cooper and Ramsdell, Jr., the boy was etherized, I then endeavored to cut or shave these granulations off and did succeed with a few, but finding that process unsatisfactory, I took a pair of new and sharp v. Græfe's fixation forceps, and taking up each body separately, between the teeth, I first pressed them tightly and then twisted the bodies off. This process was quite slow and took some time, but it seemed to be doing the work very effectively. I removed all that I could see, and then applied an 80-grain solution nitrate of silver. The boy recovered from the ether well, enjoyed a good night's rest, with little or no reaction in the lids nor ecchymosis in the surrounding tissues. Afterward he had constant daily applications of various astringent preparations, but with no return of his trouble, and left for home with instructions to use a mild spray of tannic acid and glycerine, applied daily.

The appearance of the everted lids in this case was very peculiar and difficult to describe, being quite different from any case I ever saw, and being so devoid of any proper blood supply that it was impossible to stimulate the absorbents so as to cause these hard, cartilaginous masses to disappear with any possible applications. I was well satisfied with the result, and should at once adopt it in any similar case.

233 East Thirty-fifth Street.

Mosquito Oil.—A correspondent from Sheepshead Bay, a place celebrated for the size of its mosquitoes and the number of its amateur fishermen, recommends the following as a very good mixture for anointing the face and hands while fishing:

Oil of tar	1 ounce.
Olive oil	1 "
Oil of pennyroyal	½ "
Spirit of camphor	½ "
Glycerine	½ "
Carbolic acid	2 drachms.

Mix. Shake well before using.—*Ex.*

MULTIPLE TUBERCULAR TUMOR OF THE BRAIN CAUSING EPILEPSY.

By H. E. ALLISON, M.D.,
WILLARD, N. Y.

F——, aged sixteen years, suffered from epilepsy for more than three years, and was extremely demented. His previous history is unknown. He was wet and dirty at night, and frequently during the day. His convulsions occurred at intervals of from two to three weeks, and then a storm of several would take place, leaving him very dull and very stupid for several days. At all times he was irritable. He walked about the hall with a tottering gait and a tendency to fall forward, and talked in a shrill, unintelligible manner, while the saliva constantly ran from his mouth. He had dark hair and eyes, fair skin, full habit, and showed the usual physical signs of scrofulosis to a marked degree. For several months before his death he had suffered from suppurating glands of the right axilla, involving the whole chain, with much discharge, and also from tuberculosis affecting both lungs. During the progress of the disease, he suddenly passed into a state of stupor, and died in a few hours.

At the autopsy the glands of the mediastinal space were found enlarged, and under the upper portion of the sternum a pasty mass of cheesy matter was found, about an inch in diameter. The lungs on both sides were firmly adherent throughout their

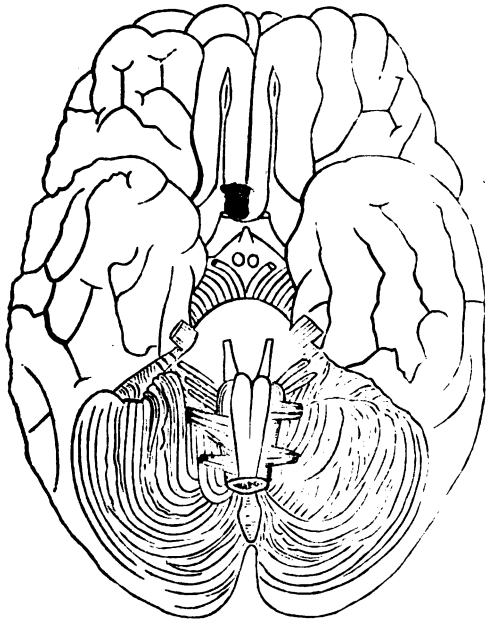

FIG. 1.—Showing tumor compressing optic nerve.

whole extent and infiltrated with pus, and tubercular matter was thickly and evenly distributed through them. A large abscess was found in the middle lobe of the right lung.

Upon examining the head, the eyelids were found glued together with a thick exudation. The calvarium contained two marked depressions on either side of the longitudinal fissure corresponding to the situation of Pacchionian bodies, and at these points the skull was very thin and translucent. The cavity of the skull contained several ounces of serum and the arachnoid was greatly thickened, so that it could be removed in large sheets like the lining membrane of an egg-shell, and was very thick and opaque, especially about the cerebellum and base of the brain. At the apex of the right middle lobe was a cyst containing about two drachms of serum, and at this point the convolutions were wasted, causing a marked inequality between the two sides. A small tumor was found just at the entrance to the right optic foramen compressing the optic nerve at this point, but not involving its substance.

This tumor was about the diameter of the nerve, and communicated with another tumor about the size of a bean, grayish pink in color, and situated in front of the optic chiasm in the right side of the longitudinal fissure. The latter was surrounded by a mass of softened tissue that was washed away by a gentle stream of water, leaving the tumor in a cavity the size of a chestnut, and showing as its only connection a small artery from the anterior cerebral. The surface of the tumor was uneven, and its appearance was as if it were covered with pale granulations. The whole substance of the brain was softened, and upon placing it upon its base, it spread apart, tearing through the central commissures nearly to the base. Another tumor was then seen on the right side close to the gyrus fornicatus, one and one-fourth by seven-eighths inches in diameter, and adherent to the membranes that dipped into the sulcus.

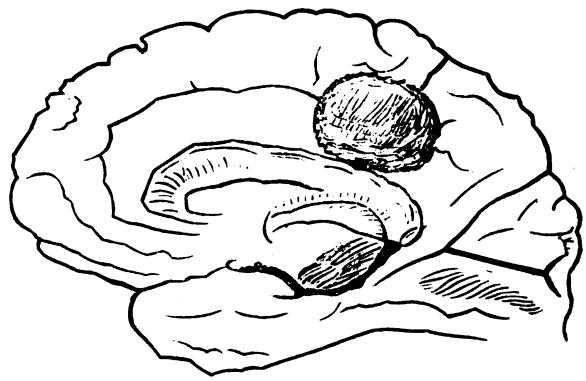

FIG 2.—Showing tumor on right side.

It encroached upon the right hemisphere, but was loosely attached to the brain substance, and did not involve the ganglia beneath it. The surface of the tumor was hard and nodulated, and when sawn in halves it disclosed a calcareous shell and an interior filled with dry, cheesy, and hard calcareous matter. At the base of the right corpus striatum there were evidences of a recent clot extensively involving that body, and this with the subsequent effusion was the immediate cause of death.

The case is interesting as showing the dissemination of caseous matter throughout the lungs, the brain, and the lymphatic glands and as being the probable cause of epilepsy. I have observed three other cases of cerebral tumor, in two cases causing epilepsy. One in a middle-aged man, in whom the tumor produced a series of convulsions continuing for several years, during which time he continued to perform his literary duties, though his mind became somewhat impaired before death; and one in a middle-aged woman who had convulsive seizures of the nature of epilepsy for many years, and upon

her death a very large tumor, about two inches in diameter, was found in the frontal lobes and lying upon the sella turcica; and in the third case the tumor was at the base of the brain between the pus and optic chiasm, producing epileptoid convulsions only for a short time before death.

INTERNAL DERANGEMENT OF THE KNEE-JOINT.

By J. J. BERRY, M.D.,

LATE INTERNE ST. FRANCIS HOSPITAL AND HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

In an interesting paper read at a recent meeting of the Academy of Medicine, Dr. Lente described a condition of the knee-joint which, to my mind, bears a strong resemblance to the injury indicated in the title of this article.

Various interpretations have been placed upon these less important accidents. Brodie attributed such symptoms to loose cartilages within the joint. Verneuil found similar signs of traumatism in rheumatic subjects. Hey has given a more satisfactory description than most of the causation of those symptoms which we so frequently meet with.

By internal derangement of the joint is meant an imperfect apposition of the articular extremities—a slight form of dislocation which is hardly enough marked to produce evident external signs, but is of sufficient gravity to demand immediate relief. Knott, in a paper read before the University Biological Society of Dublin, explains the nature of the lesion as produced by a combined twisting and lateral movement conveyed to the knee at a moment when the ligaments are in as lax a state as possible. As a result, the margin of the condyle is lifted over the edge of the semi-lunar cartilage. He has found, as an outcome of this displacement, two prominences: an internal, formed by the projecting lower margin of the internal condyle; an external, produced by the upper edge of the tibia with its attachment of semilunar cartilage. These two points are tender on pressure and, being readily distinguished, are of some diagnostic importance. That displacement of the cartilage can ever be produced by such incomplete dislocations there seems to be no direct evidence.

Very insignificant causes combine to produce this injury, most frequent among these being indirect violence, such as stubbing the toe while the limb is in a semiflexed position. The displacement may exist only for a moment, and may then be overcome by the attempts of the patient to recover his equilibrium or to stand again upon his feet. If, however, a proper apposition of the articular surfaces does not at once occur, then does pressure upon the cartilages and tension of certain ligaments produce the various reflex phenomena which are at times so persistent and troublesome. Even when spontaneous reduction takes place there may be resulting sequelæ, as stiffness and effusion.

Rotatory movements of the knee-joint, which are normally considerable, are liable to produce contusion of the synovial membrane and resulting inflammatory reaction. I have noticed in many cases of knee-sprain a small synovial effusion which usually disappears in a few days, even without treatment, but in certain cases there results secondary changes from which it would not be difficult to trace the pathological evidences of chronic synovitis. To determine whether an injured joint was previously in a healthy condition is at times difficult, for there are rheumatoid inflammations which progress insidiously until a blow or sudden wrench detaches a synovial concretion, or incites changes in the cartilage or synovial membrane, which render the character of the lesion at once unquestionable.

I have thought it less advisable to consider *en detail* the physical signs of these lesions, than to indicate in a very brief way the anatomical basis of symptoms which are not only protean, but sometimes contradictory.

South Norwalk, Conn.

A CASE OF SUDDEN DEATH AFTER CONFINEMENT.

By U. O. B. WINGATE, M.D.,

[WELLESLEY, MASS.

In The Medical Record for July 8, 1882, Dr. E. P. Hurd, of Newburyport, Mass., reports two cases of sudden death after confinement, one occurring in his own practice, the other in the practice of Dr. George W. Snow, of Newburyport, Mass. The following case occurring in my own practice may serve as a companion to the above named cases.

Early in the morning of July 12, 1880, I was summoned to attend Mrs. F—— in confinement. The lady was an American, twenty-six years of age, healthy and robust, weighing nearly two hundred pounds. She had given birth to four children at full term. Her children were all large at birth, none of them weighing less than eleven pounds. Some two years before this I had attended her in her fourth confinement, and delivered her of a child weighing twelve pounds. A year after I delivered her of the products of a false conception in the shape of a fleshy mole. On my arrival I learned that the patient had been in pain, more or less, nearly all night. Vertex presenting; os slightly dilated; parts moist and in good conditon. The pains were regular and of good strength. At ten o'clock A.M. a large bag of water had formed, which I then ruptured, and a large amount of water came away with each pain. At eleven o'clock A.M. the patient was getting very tired and asking for help. The head was high up in the L. O. A. position; os well dilated. I found the pulse showing marked signs of exhaustion, and the pains, though regular, were making no progress. Assistance at this hour of the day was not at hand; the day was excessively hot, and the patient refused ether. I at once applied the long forceps, and commenced the hardest task I ever undertook in the lying-in room. By the assistance of the husband, who grasped me about the waist from behind, my hands being wound by a towel to the handles of the forceps, I finally succeeded, at eleven thirty o'clock, in bringing into the world a dead female child which weighed seventeen pounds.

There was but slight laceration of the mother. Stimulants and ergot were administered; the placenta soon came away, and the patient rallied well. She seemed very cheerful and grateful that she had been delivered alive, and while I was working over her in arranging dry clothing, she raised a towel and wiped my face, which was dripping with perspiration.

I remained with her an hour and then went home to obtain some refreshments. I had been at home but a short time when a violent ring of my bell brought me to the door, where I met the husband,

who stated that his wife was dying. I hastened to her bedside, but a short distance, and found her dead. The nurse informed me that she was comfortable up to the time the husband came for me. She then suddenly complained of a sharp pain in the cardiac region, breathed very quickly, turned dark in the face, and at once expired. This occurred about two and a half hours after delivery. No autopsy could be obtained. I could but regard the case as one of cardiac embolism.

I refrain from commenting on the causes of this sad termination of life, as theory is far more rife than fact.

Reports of Hospitals.

ROOSEVELT HOSPITAL, NEW YORK.

SERVICE OF DR. W. H. THOMSON.

(Cases reported by HENRY LONG TAYLOR, M.D., House Physician.)

SINGULTUS TREATED BY NITRITE OF AMYL.

PATIENT, male, forty-one years of age, glass polisher, admitted June 26th, was in Roosevelt Hospital in March and April, 1881, with obstinate and persistent hiccough. Discharged cured at end of that time. No record found of treatment then employed.

Had been well till three weeks ago, when began to hiccough, and has kept it up day and night ever since. Keeps him awake at night, otherwise well. Hiccoughs several times a minute. Urine, 1,025, acid, no albumen. Bowels regular. No known cause. Does not know of other glass polishers having hiccough. Dr. Thomson ordered Paquelin's cautery applied along back of neck from third to seventh cervical vertebræ, and atropine, gr. $\frac{1}{60}$, injected into nape of neck. This was done several times, the cautery relieving him for a few hours; the atropine did not stop the hiccough. On June 29th and 30th, chloroform, ℥ xx.–xxx. were given. No relief.

Hiccough has stopped spontaneously for some hours several times, generally in early morning.

July 1st.—A pearl of amyl nitrite was inhaled with effect of stopping paroxysms immediately.

July 5th.—No recurrence since the one exhibition of amyl nitrite (July 1st), except a slight attack yesterday, which was stopped by the nitrite of amyl.

THE HARMLESSNESS OF HYPODERMICS.

Hypodermic injections of various substances are used in moderation in Roosevelt Hospital, according to indications. I never in my fourteen months' residence in the hospital saw them followed by any worse effect than a little local redness and induration, and this in only one or two instances. There have been given in the medical service during this period more than three thousand hypodermic injections of different substances, such as Magendie's solution, Magendie and atropia, atropia, Lente's solution of quinine, whiskey, digitaline and whiskey, ether, carbolic acid, etc., and these have not been followed by abscess in a single instance, and I can only remember one case where there was any inflammatory induration, and this seemed to be idiosyncrasy, as on using fresh solutions and clean needles, subcutaneous and parenchymatous injections both produced the induration, which, however, resolved.

A patient, male, aged ——, with spasmodic asthma, whose attacks can only be controlled by morphia, has had three hypodermics a day on the average (often six) for about thirteen months, certainly over one thousand hypodermics, and never has had the least local trouble. Parenchymatous injections are preferred and are practised in the majority of cases.

Our solutions are not always fresh, and often contain confervæ, and there is no special pains taken to clean the needles. Solutions over a month old and full of confervæ have frequently been used.

Our solutions of Magendie and atropia contain gr. ss. of salicylic acid to the ounce, and remain tolerably clear for several weeks. Does this prevent the growth of other ferments more nocuous than algæ?

ST. MARY'S HOSPITAL, LONDON.

CASES UNDER THE CARE OF MR. HAYNES WALTON, SENIOR SURGEON TO THE HOSPITAL.

CASE I.—*Extravasation of urine—Impacted stone.*—P. P——, aged two years, was admitted on October 29, 1881. He was brought to the hospital supposed to be suffering from rupture. The penis and scrotum were found to be enormously distended and presented a shining, semi-transparent appearance. His mother said that this had come on since the previous night and he appeared to have difficulty in passing his water. Had made water freely the night before.

October 29th.—Chloroform was administered and the prepuce slit up.

A small stone was found to be lodged just inside the prepuce. After much difficulty a catheter No. 2 was passed and the urine drawn off. Mr. Pye opened the urethra freely in the perineum. A hard deposit, supposed to be phosphatic, was found in the urethra, but could not be removed as it was close up to the bladder. Scrotum incised to allow drainage. Poultices.

October 30th.—More incisions made in the scrotum and one in the penis, which seemed to puncture the urethra, as immediately it was made there was a gush of urine. The perineal incision into the urethra was closed up. Very little urine passed until this extra incision was made into the urethra. Water only passed by making forcible pressure above the pubes. Poulticed.

October 31st.—Poultices continued and hot baths given. Urine continues to come away only on pressure over the bladder and only by the second incision into the urethra.

November 1st.—He seemed much better. Swelling subsiding and urine passes without pressure.

November 20th.—Poultices to be left off.

November 21st.—Water dressing instead.

November 26th.—Dry dressing.

December 1st.—General appearance improved. Intellectual faculties developing.

December 10th.—Swelling on back of neck on right side.

December 11th.—Poulticed.

December 25th.—Discharged.

CASE II.—*Phlebitis of leg—Popliteal abscess.*—W. E——, aged nineteen, his family history is good. Father living and mother died after her confinement. He is a tolerably strong, healthy-looking youth of fair complexion, rather thin. He has never had any illness to cause him to keep his bed. Present illness. About two months ago he walked

forty miles in eighteen hours, and at the end of his journey found his left heel to be very sore, but did not give up his usual work as a builder's laborer. On October 28th, he had been standing for several hours sifting some damp earth, and toward evening he found much pain in the left leg, accompanied with swelling just below the knee. At bedtime the swelling had much increased, as well as the pain, and he did not get much sleep during the night. On the 29th he put a linseed poultice on the leg over the seat of pain and sent for a doctor, under whose treatment he remained for a week. At the end of that time, finding he was no better, he came to the hospital and was admitted on November 3, 1881. He was found to have a hardening of the veins in popliteal space, a good deal of swelling and tenderness in the upper part of the calf of same leg. There was a small abscess in cellular tissue, which was opened, letting out a small quantity of matter. A poultice was then applied. He was unable to stand and the knee-joint was partly flexed. Tongue was coated and bowels confined. Temperature (evening), 99.6°. Diet simple. Beef tea O. j. Ordered, pil. hyd. c. col., gr. x., statim; mist. quinæ, ℥ j., t. d. s.; cataplasma lini.; pil. opii., gr. j., (at bedtime). The temperature rose to 100° on the 4th (evening), and 101° on the evening of the 5th. On the 6th it fell to normal and did not rise again.

November 6th.—Abscess in calf has been continually poulticed, but does not diminish in size. This morning it was cut into and about two ounces of pus were let out. A poultice again applied. The veins in popliteal space are still very hard and tender. Temperature last evening, 101.2°. This evening, 98°.

November 10th.—Since the abscess was last opened he has been feeling much better; he has very little pain now, the veins are somewhat hard still. There is no discharge now, poultices are discontinued. Tongue much cleaner. Bowels open. Temperature normal. The leg is still somewhat flexed at the knee-joint.

November 17th.—Veins are much softer and not so painful on pressure. The knee-joint is still somewhat flexed and he has pain if he puts the foot to the ground. The wound where the abscess was has entirely healed.

November 24th.—He is much better, has been up the last few days, sitting with his leg in a chair. He has very little pain now when he puts his foot to the ground.

December 2d.—He has been wearing a patella splint for the last few days, and has been walking about the ward a little each day, has no pain now, and the foot does not swell.

December 7th.—Discharged. He has quite recovered, but the joints are rather stiff. He still has a bandage on over the knee-joints.

Case III.—*Pelvic peritonitis and abscess in loin.*—P. F——, aged twenty-six years; married nearly two years; one child. Family history good. Always enjoyed good health up to the time of her confinement in February, 1881. Since then menstruation has never occurred, but she has had a continuous discharge, which has frequently been very foul, but more so for the last month.

Last July she felt a pain in right hip and leg as far down as the knee. At the same time she noticed a swelling in the right hip and groin which occasionally extended for some way down the thigh. She had a yellow discharge about two months before her confinement. The child was weakly and only lived five months. On manipulation of tumor, crepitus is felt, showing the presence of air in the tumor. She was admitted on October 31, 1881, temperature 100.6°. On November 8th the tumor was explored with a hypodermic needle and a small quantity of thick yellow pus and some gas drawn off.

November 9th.—An incision was made by Mr. Walton and a quantity of very offensive pus let out. Incision about three inches behind right anterior superior spine of ilium. Temperature (evening), 101°.

November 10th.—She feels very much easier. Temperature fallen to normal; 100.2° in evening.

November 26th.—Slight bagging has taken place just behind the opening. Temperature (evening), 103°.

November 29th.—Feels easier. A quantity of matter discharged from the opening enlarged by Mr. Wood. Temperature normal.

December 2d.—Feels much better. No pain.

December 4th.—Got up for the first time for an hour.

December 6th.—Discharge has increased again and more pain.

December 9th.—Better, very little discharge.

December 12th.—Continues to improve.

December 17th.—Discharged, cured.

Case IV.—*Dislocation of elbow and fractured humerus.*—C. R——, aged fifty-three, was admitted on November 19, 1881. He was in the hospital about seven years ago for an injury to his foot.

Present illness: he was knocked down by the pole of a luggage-van striking him on the right shoulder. He was thrown forward on his face, one of the wheels passing over the right arm and right leg. He was brought to the hospital at once and on admission was found to have fractured the shaft of the right humerus obliquely about the middle. There was also a dislocation of right elbow-joint "backward." The right foot was much buised, but no skin broken. There was a slight superficial wound on the inner side of right knee. He appeared to be in much pain. The dislocation was reduced by the house-surgeon. The arm was put up on an internal angular splint and he was put to bed with the arm raised on a pillow. He was not under the influence of drink when admitted.

November 20th—At 2 A.M. he had not had any sleep and was still in great pain, so he was given a hypodermic injection of morphia, gr. ¼, after which he slept for several hours. Ordered pil. hyd. c. col., gr. x., statim.; haust. alb., ℥ ij. Diet simple; milk, O. ij., beef-tea, O. j.

November 21st.—He seemed comfortable and does not complain of much pain. There are several large blebs on different parts of the arm. The whole arm and hand are swollen but not much discolored. He slept tolerably well last night. Pills acted very well. Tongue clean. Temperature, 99°.

November 23d.—The arm and hand are more swollen and more painful. The splints were removed. There were several large blebs, some of which had burst, leaving a raw surface. There was not much displacement of the bones at the seat of fracture; so the sore surface was powdered with starch, and the arm rested on a pillow and kept steady by sand-bags.

November 25th.—The swelling has much subsided and the sore surfaces are drying up. They are now dressed with zinc ointment and the arm still kept on a pillow. He sleeps well and has no pain except when the arm is moved.

November 30th.—The sore places have, with the exception of two, healed over, and the swelling has nearly all subsided. The last two days he has been allowed to sit up in bed with the fore arm in a sling, and the elbow allowed to drop. This afternoon, being ten days since the accident, the arm was again placed on an internal angular splint, and on the outer side an india-rubber splint was moulded to fit the arm, reaching from the top of the shoulder to the wrist, holes being cut in the india-rubber over the sore places. The two splints were then strapped on the fore-arm as far as the elbow and a bandage applied. Extension was then made so as to prevent overlapping of the fractured ends of humerus and the upper angles of splint, then firmly bound together. External to the india-rubber splint an angular tin splint, about two inches wide, was strapped on, so as to strengthen it, and the limb well bandaged, leaving open the two sore places so that they may be dressed each day.

December 1st.—He has had a good night and is feeling very comfortable this morning. The arm is not swollen and appears to be in good position. The discoloration of foot has entirely disappeared and the sore place on knee has entirely healed.

December 4th.—Vaseline ordered to be applied.

December 7th.—Arm is still comfortable and not much swollen. The sore parts are dressed daily with vaseline. There is not much discharge from them now. He has been up each day since the 3d for a few hours. Sleeps much better. Appetite good.

December 10th.—The tissues on front of elbow-joint are looking much inflamed and there is much swelling around. Poulticed since yesterday. The other small wound on back of arm is healing up fast. Has had two rather sleepless nights and the arm has been rather painful. Bowels regular.

December 18th.—Sore parts on front of elbow less inflamed and not so painful. There is a large superficial slough which is getting detached. Poultices continued.

December 22d.—Bandages and splints were all taken off this morning. There is good union of the fractured humerus, and the bones are not overlapping. It is in very good position. The slough at elbow has partly come away. A clean padded angular splint was applied to the inner side of arm and the gutta-percha to the upper arm as before. He is about the wards every day and makes himself useful with the other hand. Appetite good. Sleeps well. Bowels regular.

December 30th.—Splints taken off this morning. The wound at elbow is still poulticed, it is getting smaller. There is still some of the slough remaining. Wound looks otherwise healthy. A new splint composed of brown paper was moulded to the upper arm, so as to give support to the part that has been fractured. The angular splint has not been re applied but the arm kept in a sling. The elbow-joint is inclined to get stiff. He is quite well in general health.

January 5, 1882.—Discharged cured.

Vivisection Laws in England.—The absurdity of the English law against vivisection is well illustrated by a remark of Sir James Paget. He says: "I may pay a rat-catcher to destroy all the rats in my house with any poison he pleases, but I may not myself, unless with a license from the Home Secretary, poison them with snake poison."

Progress of Medical Science.

Orthopœdic Deformities of Infancy and Early Childhood.—The July number of the *American Journal of Obstetrics* contains the first of a series of articles upon the above subject, by Dr. Chas. F. Stillman, prepared as practical guides for the practitioner in the treatment of these conditions. The first subject is that of "Infantile Talipes Varus." Dr. Stillman condemns the practice of indiscriminate tenotomy, asserting that no proper excuse for its employment exists, except when *permanent* curative effects are expected to follow the *permanent* weakening of the muscles which tenotomy produces. The expediency of this operation is a matter requiring judgment and experience, because if the condition contra-indicates the operation, the temporary relief of the deformity is sure to be followed by the relapse seen in so many cases. Dr. Stillman advises the use of other means at the outset of treatment, tenotomy to be considered as a *dernier resort*; also the gradual reduction of the deformity by the hands of the practitioner, an assistant putting the parts upon the stretch meanwhile, the foot between such attempts to be held in the plaster-of-Paris and adhesive plaster dressing, or in an accurately moulded felt splint, to retain what is gained at each reduction. When the foot can be placed at its natural angle with the leg, elastic power is to be used. An outwardly inclined flat spring attached to the side of the baby's shoe is employed to keep the foot from turning under, while appropriate rubber cords are attached from spring to shoe. By means of this simple splint the deformity is more quickly cured the more exercise the little patient is allowed to take. Dr. Stillman depreciates the heavy, cumbersome, split-soled club-foot shoes now in use, as adding weight and incorrect mechanism to the existing difficulties of the deformity, and criticises the Barwell system of elastic cords as being injurious to the nutrition of the muscles of the leg, and not fulfilling all the mechanical indications. The various procedures for the successful treatment of the condition are detailed with the exactness of experience, and will prove of practical service to the practitioner. In regard to bow-legs, which is the next subject considered, Dr. Stillman advances some original ideas regarding its nature and treatment which are well worthy of attention. The application of spring bows as an element of treatment in these cases is advocated and practically considered, the centre of the bow of the spring to be placed against the centre of the bow of the leg, thus opposing one curve to another. This forms a light and effective brace, which is more valuable than the rigid braces now employed, because more physiological. The paper is illustrated by several woodcuts.

Treatment of Gonorrhœal Orchitis by Position and Laudanum Embrocations.—Dr. Rocha (*Riv. Ital. di Ter. e Igie.*) has obtained very happy results in the treatment of gonorrhœal orchitis. He places his patients in the dorsal or lateral decubitus, and elevates the testicle gently by a pad which adapts itself to the movement of the patient. Every two hours he applies to the affected member an embrocation containing five to eight drops of Sydenham's laudanum. Under this treatment, orchitis, which has begun with the greatest intensity and acuity, disappears in eight, and sometimes in

four days. In the subacute and chronic forms, in which there is no pain, laudanum invariably produces favorable results with safety and speed. Testicular induration, ordinarily of slow resolution, has been observed to disappear entirely under the influence of laudanum, in fifteen days. Thirty cases have been cured in this way without general symptoms, due to absorption of the drug. A slight somnolence, easily yielding to coffee alone, was observed. Although Dr. Rocha does not pretend to explain the therapeusis of laudanum in orchitis, he thinks its action is altogether local. Alimentation is to be regulated according to the degree of the fever.—*La Cronica. Med.*, June, 1882.

A Good Way to Obtain the Juice of Meat.—M. Stanislas Martin (*Bull. gén. de Thér.*) recommends the following convenient and cheap procedure: Take of beefsteak one kilogramme, chop it, and reduce it to a thick paste in a mortar, then add gradually 250 grammes of warm bouillon, or, in default of this, ordinary water. Stir the mixture, place it in a piece of linen and express it. The juice obtained is evaporated in the *bain-marie* until the 250 grammes of water or bouillon added have been dispelled. If the operation has been well conducted, and the temperature has not been too high, the microscope will discover in the cold juice all the blood-corpuscles which constituted a part of the meat, and also osmazone and other soluble principles. The gentle heat of the *bain-marie* will have removed the repugnant odor of blood without impairing the nutritive value of the juice. In order to prevent rapid alteration of this bouillon, two modes of procedure are recommended. The first consists in pouring the juice into small flasks warmed in the *bain-marie;* when the water becomes too hot to the touch, they are withdrawn and tightly corked. Or, secondly, if no contra-indication exist, a syrup may be made as follows: add to 200 grammes of the juice 380 grammes of sugar. Keep the syrup thus prepared in a vessel protected from the air.—*Revue Medicale*, June 24, 1882.

Treatment of Serpents' Bites.—Dr. Monteiros publishes an article upon this subject in the *Gazeta Medica da Bahia* of March, 1882. He refers to the important discovery of Dr. de Luceda in regard to the value of the permanganate of potassium, but indicates a line of treatment to be followed in the absence of this remedy. Drs. de Miranda and Jardine, his colleagues, he states, use brandy in sufficiently large doses to produce well pronounced stimulation. Dr. Miranda alternates alcohol with two or three drops of ammonia in sweetened water. Dr. Monteiros employs the alcoholic potion of B. Toll, administered in drachm doses every hour, or in two-drachm doses every two hours, alternating with two to three drops of ammonia. He has never had a fatal case with this treatment, nor have his colleagues had any. The wonderful efficacy of the roots and leaves of many plants popularly used in serpents' bites, he attributes to the alcohol with which they are administered. He speaks of the recognized good effects of energetic exercise as antagonizing the action of the poison by increasing diaphoresis and stimulating the heart. The fundamental principle of treatment should not be lost sight of, namely—alcohol should never be used except in therapeutical doses. The action of alcoholics upon the nervous system clearly establishes the vital differences between the effects of therapeutical and toxic doses. Alcohol neutralizes the serpent's poison, not as a proper antidote, but because it stimulates the secretions on the one hand, while on the other it arouses the nervous system and prevents collapse. Todd's formula, employed in various morbid affections, is to be preferred.

Muscular Action in Pathology of Hip Disease.—In the July number of the *New York Medical Journal and Obstetrical Review*, Dr. A. B. Judson, Orthopædic Surgeon to the Out-Patient Department of the New York Hospital, discusses some points in the morbid anatomy of hip disease, with special reference to the supposed effect of muscular contraction in promoting the progress of pathological changes in the articular structures. A careful review of the most important observations on record leads him to the inference that the crowding of the articular surfaces together by muscular action has no such effect. What mainly points to this inference is the fact that the primary lesions are not usually to be found in the superficial structures that enter immediately into the formation of the joint, but rather in the cancellous texture of the bones. This conclusion, however, casts no doubt upon the utility of the extension treatment, but simply leads to this interpretation of its beneficial action: aside from the fact that we are compelled, empirically, by reason of its anodyne quality, to use traction, there is ample rational ground for its use. Traction, however applied, is unavoidably accompanied by fixation. The most efficient apparatus for the application of traction is, at the same time, the most efficient means known to surgery for the solution of that difficult problem, the immobilization of the hip-joint; and, finally, immobilization is indicated by every feature of the pathology as revealed in morbid specimens.

Action and Uses of Antipyretic Medicines.—Prof. Binz expresses his views on antipyretics as follows: In the present state of our knowledge there are two modes in which antipyretic medicines may be conceived to operate; first, by increasing the discharge of the pyrexial heat; secondly, by checking its production. The quantity of heat discharged may be augmented by direct withdrawal (tepid water), or by facilitating the circulation through the skin (digitalis, cutaneous irritants). The production of heat may be lessened by repeated cooling of the surface, and especially by the internal use of antizymotics.

Febrile diseases commonly owe their origin to the introduction and rapid development of substances akin to ferments. Several of these have been shown to resemble yeast in being low vegetable organisms, or derived from such organisms. They enter the glands, where they undergo multiplication, increase the metabolic processes, generate products of decomposition which exert a paralyzing action on the nervous system, and raise the standard of temperature throughout the body. Owing to impaired action of the heart in certain stages of the disorder, or to contraction of the cutaneous vessels, the skin becomes anæmic, and gives off less heat than usual. The internal temperature rises accordingly. Quinine, our chief antipyretic, acts by directly combating the efficient cause of the disorder, and by checking the abnormal metabolism going on in the body. The nervous system takes no part, or only a secondary part, in this operation. In intermittent fevers quinine prevents the paroxysms by attacking their infective cause. The paroxysms are not the essence —the substantive element—of the disease; they are

only a symptom of it. The substantive element is the poison deposited in the colorless corpuscles of many organs, especially the spleen. There are fevers without paroxysms, and paroxysms without fever. It is just those intermittent fevers which run their course without paroxysms that are the most malignant. The malarial poison rapidly causes disintegration of the tissues and the blood, and so paralyzes the nerve centres. The reduction of acute splenic tumors by quinine depends upon the adverse influence exerted by the alkaloid on the infective poison to which the morbid over action of the spleen and its consequent enlargement are due. "*Cessante causâ cessat effectus.*" Even a healthy spleen may be reduced in size by large doses of quinine, the alkaloid vigorously checking the oxidation of its principal elements, the colorless corpuscles. Quinine has no direct influence on the vaso-motor nerves. Quinine attacks the malarial poison with especial energy. On this fact depends the so-called specific action of quinine on intermittent fevers. The same relation, but in a minor degree, subsists between quinine and the infective poison of enteric fever, between mercury and iodine and the poison of syphilis, between salicylic acid and the 'irritant' in acute articular rheumatism. An antipyretic which, in one disease, instantaneously arrests the fever, may be wholly powerless in another. The difference depends on the fact that the various antizymotics act very unequally on the individual schizomycetes and ferments; one will paralyze them rapidly, by another they will hardly be affected. The past history of therapeutics and recent achievements in the domain of etiology and pharmacology, entitle us to assume that, by persistent scientific inquiry and practical observation, we may succeed in discovering a specific antidote for every species of infective or septicæmic malady.

Treatment of Chronic Dysentery by Large Enemata of Nitrate of Silver.—In the *Lancet*, April, 1882, Dr. Stephen Mackenzie reports four severe cases of chronic dysentery, which were rapidly and effectually cured by one, or at the most two, injections of nitrate of silver, in the proportion of one drachm of the nitrate to three pints of water. Twenty years ago this plan was much more frequently employed than it has been of late years. It was then found to be equally efficacious in acute and in chronic cases. In the *Lancet*, June, 1876, a case is reported in which several American medical men introduced a speculum into the rectum under anæsthetics, and freely cauterized the mucous membrane as high as they could reach, and with marked success.

A Painful Affection of the Wrist.—In the July number of the *New York Medical Journal and Obstetrical Review*, Dr. Edward H. Bradford, Surgeon to Out Patients, Boston City Hospital, relates three cases of a painful affection of the wrist, the features of which were: pain referred to or most severe in the middle of the carpus; slight swelling; an absence of constitutional disturbance, and with no interference, or but partial interference, with motion of the articulation between the carpus and the radius and ulna. The symptoms were relieved by fixation, and recovery took place finally after a period of rest. Judging from analogy, Dr. Bradford remarks, it seems probable that the cases here reported were similar to a degree to a synovitis of the medio tarsal joint, described by Gosselin under the term tarsalgia adolescentium; differing somewhat in their course from the fact that the wrist, a part easily immobilized from the first, and not the tarsus, was affected. Leaving out of account the smaller synovial membranes of the carpus—*i.e.*, those between the pisiform bone and the cuneiform, the trapezium and the metacarpal bone of the thumb, the ulna and the fibro-cartilage at the joint—there are two large synovial sacs, viz., that between the main carpal bones and the radius and cartilage covering the ulna, and that between the main bones of the carpus, of which the os magnum is the larger and central bone. From the symptoms in the cases reported, the author thinks that the inflammation was one affecting this latter synovial sac, and limited to this alone, and that they may therefore be termed cases of synovitis of the carpus.

The Segmental Nature of the Spinal Cord.—The spinal cord may be regarded as composed of a series of segments, indicated by the pairs of spinal nerves. According to Lüderitz (*Lancet*, July 8, 1882), this view of its structure is morphologically correct. The spinal cord of the ringed snake shows a slight rounded swelling opposite each pair of nerves, which lies above the junction of the respective vertebræ, and constantly corresponds in height to the middle of a segment. The enlargement is due chiefly to that of the gray substance, but partly also to that of the white, and to an increased size of the so-called lateral group of cells. The demarcation between the segments cannot be exactly determined, but they are longer in the middle of the cord and shorter toward the extremities, especially toward the basal portion. Similar segmental swellings are to be discerned in the spinal cord of the rabbit, even on naked-eye examination. Careful microscopical measurements of the areas of the several constituents of the cord in transverse section show an analogy between these elemental segments and the swellings of the cervical and lumbar enlargements. The middle part of each segment, for instance, bears a similar relation to the extremities of each segment, when the area of the constituent columns is compared. The increase in size at the middle of each segmental swelling is greater in the transverse than in the antero-posterior diameter. The gray substance is enlarged in all directions, but especially in width. The spinal cord of man, however, presents no segmental swellings, and its elements can only be recognized by the intervals between the series of nerve-roots which arise from it. These intervals are larger between the posterior roots than between the anterior, being greatest in the middle and lower dorsal regions.

Extirpation of Organs and Tumors of the Abdomen by Means of the Elastic Ligature.—An important communication on a new method of operating has just been made by the gynecological clinic of Professor Hegar in Freiburg. It would seem that a means has been found by which total extirpation of organs of the abdomen, *e.g.*, the spleen, kidneys, perhaps even of the liver, can be undertaken without very much danger. Hegar was led to use the elastic ligature in the treatment of intraperitoneal fibroid pedicles by the very favorable results he previously achieved in thus treating extraperitoneal fibroids, the danger of hemorrhage from the pedicle being by this means entirely excluded. Kasparzik, his assistant, in a communication to the *Berl. Klin. Woch.*, No. 12, 1882, has published the results of experiments upon animals, which consisted in placing pieces of elastic tubing, previously

disinfected, in the peritoneal cavity of a rabbit, and killing the animal five weeks later, when it was found that the elastic had become fastened to coils of small intestine by fibrous tissue, but not a trace of suppuration was visible. Repetition of this experiment on other animals gave the same result; therefore it was held that the elastic ligature was very well borne by the abdominal cavity as a foreign body.

A second series of experiments consisted in the tying of pieces of omentum, uterus, spleen, liver, and kidneys, partly with elastic tubing, partly with solid india-rubber ligatures, the stumps being either cut off or burnt with the thermic cautery. The results were most satisfactory in the case of the omentum and uterus, especially with the thin india-rubber ligature, which did not cut its way through the tougher tissues as it did in the case of the spleen, where much better results were obtained by the tubing. In a dog, half the spleen was extirpated, and an elastic tube put on the pedicle, which was then cauterized. Five weeks afterward, on opening the abdomen, a coil of small intestine was found closely adherent around the stump. On removing this, the ligature was found lying in a little cavity, above adhesions to the stomach. Another dog was at the time of the report still running about with one-half of his spleen tied with the tubing, the other with the solid ligature, and was to be killed later on, in order to observe the condition after a longer period of incarceration.

The liver and kidneys have not been successfully treated as yet; but Hegar is of opinion that more caution in the degree of tying and in the selection of proper tubing will later lead to success.

From these experiments, it is evident that uterine pedicles can be treated without danger by the elastic ligature, which has here to deal with a firm tissue, which can be securely tied without leading to cutting through of the constricted portion, even the ligaments being capable of being treated in this manner. Kaltenbach, at the advice of Hegar, sank the pedicle of a fibroid, secured with an elastic ligature, into the peritoneal cavity after all the most carefully applied sutures had failed to control the hemorrhage; and the patient, twelve days after operation, was progressing favorably, the temperature in the vagina being 101.1° F. Hegar uses a particular instrument for the purpose of easily controlling the amount of constriction, which is a forceps with smooth blades and rounded edges, having a spring catch to fix its jaws. For temporary ligature, this fixation would be sufficient; for permanent, it is necessary to fasten the two ends behind the forceps with a wire or silk thread, then to remove it and cut the ends short, the rubber piling itself in front of the constricting wire, and thus precluding the possibility of slipping.

THE TREATMENT OF ERYSIPELAS.—From careful study of, and extended experience with erysipelas, Dr. Lydston (*Chicago Med. Journ. and Exam.*, July, 1882) feels justified in framing the following conclusions:

In the treatment of erysipelas, in all its forms, we have to consider: First, the constitutional condition which may have predisposed to the disease; second, the lesion which has acted as its exciting cause, if the inflammation be traumatic; third, the tendency to local destruction of tissue and the formation and burrowing of pus; fourth, the tendency to the typhoid condition, proportionate to the severity of the disease; fifth, the danger of septic absorption and toxæmia; sixth, the danger of propagation by contagion; seventh, the liability to serious deformity from cicatricial contraction.

1. The first indication is to be met by measures tending to correct the cachexia present, if possible. 2. The second, by careful attention to the wound, and rigid antisepsis. 3. The tendency to local destruction of tissue is to be combated by free incisions adequate to relieve all tension, and the application of hot dressings to maintain the vitality of the part and promote absorption of inflammatory exudate, and also to relieve the pain. The possibility of pocketing and burrowing of pus should be prevented by immediate incision into all purulent collections. 4. The supervention of typhoid symptoms should be prevented, if possible, by proper analeptic and tonic measures, and the liberal use of stimulants. 5. The fifth indication calls for perfect cleanliness and prompt removal of dead tissues which might excite decomposition of the discharges and consequent septic absorption, with the adoption of antiseptic dressing. 6. Transmission of the disease should be prevented by strict isolation of the affected, cleanliness, both in regard to the seat of disease and the instruments used, and on the part of the attendants, with the conscientious use of antiseptics. 7. Deformity may be prevented by careful management of the ulcers resulting from the disease, and the judicious use of skin-grafting. Various mechanical contrivances may be necessary in certain situations, to prevent contraction.

IMMEDIATE UNION AFTER CIRCUMCISION FOR PHIMOSIS COMPLICATING SIMPLE CHANCRE.—M. Aubert reports (*Lyon Méd.*, No. 9, 1882) six cases in which he obtained primary union after circumcision for phimosis with soft chancres. In two cases there was œdema, and in one lymphitis, and abscess of the penis. The following is M. Aubert's method of operating. All the surrounding parts are cleansed with carbolic lotion. The penis is then passed through a hole cut in a large sheet of India-rubber sheeting, so that discharge and blood may not collect among the pubic hair, and so become a source of reinoculation of the wound. The patient is then anæsthetized, and all the sores which are within reach are touched with the thermo cautery. This having been done, the prepuce is divided at one or more places (several shallow cuts being better than one long one, in order that the incisions may all be included in the subsequent circumcision wound), until it can be fully retracted. The parts are then again washed with carbolic lotion, and all the remaining chancres are cauterized. The operator and his assistants now cleanse their hands, and circumcision is performed with fresh instruments and clean sponges, etc. Lastly, the edges of the wound are united with sutures in the ordinary way. No reinoculation of the wound occurred in any of the six cases; and the author suggests that, if his method of operating be adopted, circumcision is applicable not only to bad cases, but also to those where phimosis is the only complication.

EFFECTS OF MALARIA ON MAN.—In the Croonian Lectures, delivered this year by Sir Joseph Fayrer, the effects of malaria are described as follows:

In addition to the direct effects of malaria, a diathetic condition seems to be established which modifies other diseases. The effects of malaria are, indeed, most protean in form, not only in its own definite and well marked pathological processes, but

it stimulates others. The stupor of typhus, the collapse of cholera, the high temperature of isolation, the sickness of an irritant poison, the convulsions of epilepsy or of dentition, may occur in the pernicious forms. It induces anæmia and general cachexia, with structural changes in the liver, spleen, or other viscera, neuralgia, asthma, and various other symptoms of disturbed innervation and sanguification, and it also appears to be in close etiological relation with dysentery, cholera, diarrhœa, beriberi, hydrocele, elephantiasis, bronchocele, and hepatic disease. Whatever its nature may be, its action on the human economy is very striking; it affects the central nervous system, causing disturbance of vaso-motor action, paroxysms of fever, and congestion of the abdominal viscera, which may become periodic in recurrence, or pass on to structural changes in the liver and spleen, or intestinal mucous membrane. No one can have resided long in a malarious climate, such as Assam, without observing the cachectic, deteriorated aspect of the people, who, although they may never have had a single attack of fever, scarcely feel ill, and would resent being told so, are yet victims to the insidious action of the poison, and present evidences of anæmia, degenerate tissues and chronic visceral disease.

Voluntary Drunkards and Dipsomaniacs.—The difference between voluntary drunkards and dipsomaniacs consists not only in the inherited neuropathic condition of the latter, but in prolonged vaso-motor disturbance, which often persists after a spree in the latter, whereas in the former the normal vaso-motor condition affecting the cerebral circulation and cell activity is soon regained, enabling the one to abandon drink, if he will, while the other is still irresolute and unstable. Cardiac gangliopathic states, too, are often persistent, in our experience of dipsomaniacs, so that an increased heart activity and more than naturally rapid pulse are second nature to these unfortunates.

Dipsomaniacs are accordingly not safe against repeated sprees, notwithstanding their promises of reform, for many months after the liquor of the last indulgence is entirely out of them, whereas the common drinking man, without the fatal heritage, who indulges from appetite alone, may be, if the incentive to self-restraint be strong.

It is therefore only folly to create and endow reformatory hospitals for dipsomaniacs without legal provision for prolonged detention which cannot be evaded—not less than a year in all cases, often longer. The links of the chain of heredity are generally too strongly forged to be broken so easily as some imagine.

It is an organic slavery that the State undertakes to free these unfortunates from when it organizes hospitals for inebriates, and it should take care of the slave till the master relinquishes his hold, and then guard the slave in his freedom ever after, even though the right of *habeas corpus* be permitted only such a conditional hold as will not re-enslave whom the State proposes to make free, that he may enjoy the benefits of true life, liberty, and the pursuit of happiness, and bless and care for those whom he may be bound in law to care for and support, but whom he does not, and cannot take care of and maintain in his pathological thraldom.—*Alienist and Neurologist*, July, 1882.

The Assimilation of Fat.—Most physiological text books teach that the fat of the body is not derived directly from the fat of the food. But from statistical analysis Hoffmann, according to the *Lancet*, has arrived at the conclusion that the formed fat of the animal body arises not only from heterologous elements of the food, but also in part, at least, from ingested fat. Radzcejewsky concludes that the special destination of this fat is the intramuscular adipose tissue. A series of investigations, undertaken by Lebedeff in the clinical department of the Pathological Laboratory at Berlin, leads him also to the conclusion that the ingested fat is deposited unchanged in the fatty tissue of the body. Two dogs were kept fasting for a month, losing in the time about forty per cent. of their weight. Previous experiments have shown that under these circumstances all the fat of the body disappears. The dogs were then fed on a diet which consisted of large quantities of fat foreign to their own nature, and a small quantity of flesh. Both dogs regained their normal weight in three weeks, and were then killed. One had been fed on linseed oil, and from its tissue was obtained more than a kilogramme of fatty oil, which did not become solid at the freezing-point of water, and which corresponded closely in chemical characters to linseed oil. The second dog was fed on mutton suet, which had a boiling-point about 50° C., and in its body, in the muscles, about the internal organs, and beneath the skin, a form of fat was found which was almost identical with suet. The organs of each dog were free from disease. Thus it would appear that ingested fat, even such as is foreign to the individual constitution, may yet become transformed directly into the fatty tissue of the animal. Other experiments of the same investigator seem to show that this is true also of milk fat.

The Pyrogallic Acid Treatment of Phagedenæ.—The application of pyrogallic acid to phagedenic chancres is followed by such excellent results that we frequently return to the application used by M. Vidal during his service. There were in the ward two cases in which the phagedenæ had attained considerable size, and two or three applications of the pyrogallic acid sufficed to completely arrest the extension of the lesion. Two days later Vidal practised auto-inoculation in these cases and the result was negative; he has, in fact, been able to demonstrate that the liquid secreted from the wound after the use of the acid loses completely its virulence. These tests can now be made with impunity, because we have in the pyrogallic acid a means of stopping at once the progress of any injuries that might be produced. The application of the pyrogallic acid gives the wound a blackish color, about which there need be no concern. It should also be mentioned that this treatment induces about the base of the sore a slight induration which greatly resembles that observed in the syphilitic chancre, and might easily lead to error if one were not informed of this result. In cases where the wound was rather large and presented numerous irregularities or cavities, necessarily attended with considerable difficulty in applying the remedy to all its parts, instead of applying the salve he ordinarily used, M. Vidal makes application to its surface of a powder composed of one part of pyrogallic acid to four parts of starch. This application is renewed morning and evening; two successive days of the treatment generally being sufficient to completely modify the phagedenic character of the wound. The treatment is then continued by means of the subcarbonate of iron.—*Journal de Med. et de Chirurgie.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, August 26, 1882.

THE BRITISH MEDICAL ASSOCIATION.

The fiftieth annual meeting of the British Medical Association, which was held in Worcester, England, during the second week of August, was an occasion of more than ordinary interest to our transatlantic brethren. In another place will be seen a report of some of the more important proceedings received from our special correspondent up to the time of going to press.

It was determined by the members that this year the semi-centennial jubilee should be celebrated, and the place of meeting was appropriately selected as being that in which the founder of the Association, Sir Charles Hastings, lived and worked during his distinguished professional career. Consequently, most of the addresses treated of themes retrospective in character, and drew lessons therefrom for the future.

Regarding the Association itself, there is certainly nothing which can show more emphatically the results of concerted effort and singleness of purpose than are manifest in its present large membership and extended influence. Fifty years ago, with a view of uniting the profession in an active body, a small band of but fifty members assembled under the leadership of Sir Charles Hastings—the Connollys, Barlow, Kidd, Hodgson, and others. From such a beginning, it has grown to be one of the largest, most powerful, and most thoroughly representative scientific associations in the world, with branch organizations in every part of the United Kingdom, and with a membership of nearly ten thousand medical men.

The attendance at the meeting was large, and the proceedings were generally of an harmonious character. Most of the discussion in open session referred to matters more directly connected with the business affairs of the Association, the arrangement of its council of government, questions of ethical discipline, and the management of its official organ. But everything seemed to be satisfactorily settled in the end.

It will appear strange to us here, at least such as are interested in the smooth working of societies, that it is not considered necessary for the president of that organization to be ex-officio member of any of the committees. Not that such an officer is expected to be present at the meetings of these committees, but that as the head of the society, his advice on matters of importance should be sought, and his opinions respected. But there is likely to be a change in this matter in future.

In view of the feeling manifested when Dr Fothergill's motion concerning an election of the editor of the *Journal* was brought up, it would seem that some of the members are not satisfied with the manner in which that periodical is managed. Why such a feeling should exist it is difficult to understand here. The present editor has made the *Journal* what it is, and any change which could be contemplated would certainly be for the worse. It is fortunate for the Association, as well as for its recognized organ, that the able management of the latter was not interfered with.

As might have been expected from the doings of the Association last year, the homœopathic question was again brought to the surface of discussion. The debate upon the suggestions offered by the Council was quite animated, the general sense of the meeting being very properly adverse to the recognition of homœopathy as such. But there was no desire to make martyrs of any members of that sect, who might already be members of the Association, by expelling them. Hence, even among the more conservative members, there was a desire to oppose the resolution having such an end in view. The principal concern was in preventing the admission of declared Hahnemannites. This, it was shown, could be easily done, with a proper regard for the rights of all concerned. Also that the Council had the power, by a two thirds vote, to expel a member for any cause, subject to confirmation at the next annual meeting. The Association was willing to leave the responsibility of judging individual cases and acting thereon to the Council, and rejected the expulsion clause accordingly. In all this a becomingly liberal spirit was manifested.

The addresses delivered in the General Session and before the sections were elaborate affairs, and were evidently prepared with great care. It must be acknowledged that the educated Englishman has a becoming pride in doing such work well. He always dignifies his subject with an importance which he instinctively feels is due to it. Hence there is much latitude for the display of fine rhetoric and more than average eloquence. In these respects the addresses fully came up to the English average

of perfection. The choice of subjects was, however, quite limited. Each orator felt that the occasion demanded some report concerning the history and progress of medicine during the half century just passed. But the manner of treating the topics was varied, and in so far interesting. It is instructive to follow the speakers in their various trains of argument, showing the different radical stages of evolution of medical thought, from the time when venesection was the ruling treatment for all diseases, until the present, when the lancet is almost a forgotten instrument, and when other and more rational systems prevail. And yet all these changes in opinion followed the natural law of human thought. No old doctrine was overthrown before the medical mind was prepared for it, and saw clearly the line for a new departure. The extremes of opinion in one direction in the natural course of events reached a precisely opposite point in another. Hence, when venesection lost favor, it was deposed for a decidedly inactive method of treatment. Then the *vis medicatrix naturæ* was studied in connection with the natural history of disease. Expectancy became the rule in the treatment of disease, and in its turn the reactionary period is manifesting itself in the more thorough cultivation of therapeutics as a science. We are going through at present that period of conservatism in the study and treatment of disease which enables us to steer judiciously between the sins of omission and those of commission. We are learning what diseases can be shortened, or at least mitigated in severity, and are discovering more and more the special indications for the use of particular remedies. And it is such a history of progress which has been presented to us in the addresses delivered before the Association.

SANITARY INSPECTION OF HOTELS.

The occurrence of typhoid fever in one of the seashore hotels, and the consequently precipitate departure of the guests, carries with it a lesson which has many phases of significance to all who are concerned in the sanitary condition of health resorts. It is so often the case that the last straw makes the burden unbearable that no one is surprised, under the present circumstances, to find the patrons of the establishment resorting to the last expedient for safety. Although such a measure is inconvenient for both parties, it is the only practical way of enforcing upon landlords generally the necessity of leaving nothing undone that will tend to protect the health of their guests. It now seems that it is not enough that the hosts should take ordinary sanitary precautions, but that they should guarantee themselves against pecuniary loss by reducing the chances of sickness among their patrons to absolutely unpreventable causes. The experiences at Seabright have placed the question, at least with hotel proprietors, upon a purely business basis. And here, as far as they are concerned, we may safely allow it to rest, with reasonably good expectations for the future.

We cannot undertake to say whether or no the cases of typhoid had their origin in the hotel, but the reports of inspectors tend to show that there were many defects connected with the drainage of the establishment which might easily render the origin of the disease possible, and the spread of the latter reasonably certain. That it did not go farther is due to the proprietor, who promptly appreciated the danger, and at once took the usual means to avert it. But what concerns the public most is the necessity of preventing these occurrences.

The hotel proprietors are evidently ready to receive suggestions. With them the question of the actual sanitary requirements of their houses must be one of prime importance. This must apply particularly to the so-called health resorts hurriedly and cheaply built for the accommodation of summer guests. And there is room for the greatest amount of improvement in a very large proportion of them.

There is no reason why the different State Boards of Health should not devise some practical means to this end. The landlords, with the best of intentions, may not be able to act intelligently in different cases. The health boards should furnish them with all desired information, and should then insist upon an enforcement of all the necessary sanitary regulations. This can be done only by regular inspection of the premises by official experts, and by the granting of a certificate of such inspection accordingly. It is just as necessary to guard the health of the patrons of a large hotel from the dangers of bad drainage and contaminated water supply as it is to prevent boiler explosions on steamboats, or the ordinary accidents on railroads. The same precautions could be taken with the various religious camping-grounds, some of which are in a dangerously unsanitary condition. There is no doubt that hotel proprietors would gladly second any measure so directly calculated to benefit their business, while they would only be too glad to be relieved of the responsibility which any individual efforts in such a direction might involve.

CONCERNING WELL-WATER SUPPLY.

The Health Board of the State of New York has signified its intention to aid the local boards in the investigation of the causes of contamination of drinking-water as supplied by the ordinary wells. This is certainly a practical method of solving one of the most difficult problems of water supply throughout the country. The people in rural districts particularly are yet to be taught the most frequent causes of well-pollution. There is no doubt

that the board will make the best use of its facilities for the collection of statistics, and for the systematic arrangement of facts bearing upon this vital question. In sparsely settled regions where there is no danger of soil saturation, the spring or well is doubtless the safer as it is the most natural means of supply. But the contrary holds true, as we all know, where a large number of inhabitants are congregated, as in our rapidly growing villages, and where private wells abound in necessarily close proximity to privy vaults and sewers. There are many such in this State, and it would be exceedingly interesting to learn the results of some of the analyses of many of the old wells in thickly settled portions of the older towns. It is the exception rather than the rule for the towns to have any provisions whatever for sewerage except what may be obtained from the surface drainage of the gutters into the adjoining ponds or rivers. Under the circumstances the chances of soil contamination are proportionally great, as compared with cities having the regular system of underground flow. If the examination is carried on by the board with the same thoroughness as was that of the construction of school-houses throughout the State, a very interesting and instructive chapter will be added to the discussion of one of the most important questions of the time.

THE YELLOW FEVER EPIDEMIC.

An epidemic of yellow fever at present exists in Texas. During the summer a few cases were brought to or developed in some of our seaport towns. It was not until the last of July, however, that the disease fastened itself upon any single place. In the two weeks ending August 11th, there were reported ten deaths from yellow fever at Brownsville, Texas. From that time between one and three deaths have been reported daily there. The actual number of cases has not been accurately given, but it has ranged between twenty and forty per day. At Matamoras, and in several small neighboring towns, the disease has also prevailed more or less extensively. In fine, Texas is suffering from a well-established, though limited, epidemic.

Measures to prevent any further spread of the disease are being actively taken. The National Board of Health has been unable, through lack of money, to help the local authorities. Fortunately, however, the Marine Hospital Service has had put at its disposal $100,000, to be used in emergencies like the present. This will, no doubt, be judiciously expended by Surgeon-General Hamilton, whose experience and executive skill have before this been well attested. The money furnished by the Government is to be expended in caring for the sick in hospitals and in quarantining infected localities. With the aid of local authorities and volunteers, a cordon has been put about the infected districts. At date of writing this, quarantining is not complete, and there seems to be some opposition to it in a few of the smaller and less infected places. The policy adopted by Dr. Hamilton is reported to be that of not forcing a quarantine upon any town against its wishes. There is some danger in this, lest local stupidity, by refusing, for selfish reasons, a sanitary cordon, might paralyze the best efforts to limit the epidemic.

However, the disease does not yet appear to be in a very malignant form. It is not at present increasing rapidly, and it is unlikely that its ravages will become extensive. The fall months are at hand, and with them cooler weather will come. With any ordinary care, it is almost impossible that we should have any extensive epidemic of yellow fever.

Reviews and Notices of Books.

Materia Medica and Therapeutics — Inorganic Substances. By Charles D. F. Phillips, M.D. Edited and adapted to the U. S. Pharmacopœia, by Laurence Johnson, A.M., M.D. Two volumes. Wood's Library of Standard Medical Authors. New York: William Wood & Company. 1882.

The first part of Dr. Phillips' "Materia Medica and Therapeutics" was published in 1879, in the present standard series. Thus the concluding part has been but recently completed.

Dr. Phillips' method of treating his subject is to take the different minerals, acids, gases, etc., and give a description of their physical and chemical peculiarities, physiological action, therapeutical action, the different preparations, and the mode of administration. Each chapter is arranged for a nearly monographic completeness.

Dr. Phillips has been moderately successful in carrying out his plan. He has collected a great deal of information regarding each object, and he presents it well. His own observations and experiments are extensive and have enabled him to decide judiciously for the most part upon the observations of others. He states things clearly and without superfluous words. We do not know of any English work which embodies so many facts regarding the subject here treated.

It will strike the reader at once that Dr. Phillips has scoured English medical literature thoroughly for every item bearing upon his work. A good deal of matter is thus put in which is second-hand and of doubtful value. The author does not seem to know German literature except by translation. His quotations from it are not numerous, and inferences from translations and abstracts are rarely trustworthy. Dr. Phillips is evidently not well acquainted with American literature either, otherwise he would perhaps have taken Bartholow's therapeutic dicta with a little more salt, and would have strengthened the physiological part of his work by a close study of Wood. We might inform Dr. Phillips also that in this country the reference "Medical Record" indicates a weekly journal of medicine and surgery, published in New York, and that very few Americans ever heard of a London monthly which abstracts medical items for the Briton who can only read his mother tongue, and which stole its name from The Medical Record of this city some years ago.

DIET OF INFANTS AND YOUNG CHILDREN. By JOHN C. MORGAN, M.D. Philadelphia: James Hogan. 1882.

THIS is a small manual of fifty pages. It contains the usual statements regarding infant diet. The author would have cow's milk diluted rather more than is usual. He also discusses and recommends commercial infant foods without much discrimination.

HALF YEARLY COMPENDIUM OF MEDICAL SCIENCE. Edited by D. G. BRINTON, M.D. Part XXX., July, 1882. Philadelphia.

THIS is one of the best reviews of medical progress published.

L'ANNÉE MÉDICALE, 1881. Résumé des Progrès Réalisés dans les Sciences Médicales. DR. BOURNEVILLE. Paris: Plon & Cie. 1882.

THIS annual has already in its fourth year established itself as among the best. It is in small octavo form, 450 pages.

HINTS AND REMEDIES FOR THE TREATMENT OF COMMON ACCIDENTS AND DISEASES, AND RULES OF SIMPLE HYGIENE. Compiled by DAWSON W. TURNER, D.C.L. Eighth English edition. 8vo, pp. 99. New York: Macmillan & Co. 1882.

THIS ought to be a wonderful book if supervision could make it so. Twelve eminent medical men and one bishop have helped in its completion. The book is really one of the best we have seen. It contains nearly all that the laity needs to know, and is better, in our opinion, than a hundred First Aid to the Injured Societies.

CLINICAL LECTURES ON DISEASES OF THE URINARY ORGANS. By SIR HENRY THOMPSON. Sixth London Edition. Illustrated with seventy three wood engravings. Philadelphia: P. Blakiston, Son & Co, 1882.

THIS popular work is printed in pamphlet form by the American publisher and sold at a remarkably low price. The profession is familiar with the general character of the work. The present edition contains some modifications of the older text, notably regarding the subject of lithotrity. Lithotrity at a single sitting is regarded as superseding to a large extent lithotomy. The book presents in a small compass an epitome of what is known regarding the diseases of the urinary organs.

RECHERCHES CLINIQUES ET ANATOMO-PATHOLOGIQUES SUR LES AFFECTIONS CUTANÉES D'ORIGINE NERVEUSE. Avec 4 planches et plusieurs figures. Par HENRI LELOIR. 8vo, pp. 220. Paris: Aux Bureaux du Progrès Médicale. 1882.

THIS monograph shows great industry and considerable original work upon the part of its author. The subject is treated of systematically and exhaustively, the author beginning with a study of the question of the relation between skin diseases and the nervous system. In his first chapter he reviews the clinical proofs of the nervous origin of certain skin affections. Next he gives the evidence from morbid anatomy that the nervous system is involved in some of the diseases in question. In the third chapter he gives reasons for believing that certain cases of vitiligo, ichthyosis, ecthyma, acute pemphigus, cutaneous gangrene, leprosy, "le mal perforant," and herpes zoster, are of nervous origin. Some cases of eczema are thought to be of nervous origin also.

In the fourth chapter the pathology and physiology of these dermatoses is discussed. In the last chapter the importance of the subject is insisted upon and therapeutic indications are given. The work is beautifully illustrated and the author has supplied a copious bibliography.

We admire the zeal and thoroughness of Dr. Leloir's work. It is a model scientific work and is full of instructive facts. We are quite prepared to agree with most of the author's conclusions and take issue only with his theory of the (peripheral) nervous origin of leprosy. This is hardly proven.

DIE NERVOSITÄT von DR. PAUL JULIUS MÖBIUS. Illustrirte Gesundheitsbücher Leipzig, verlag von J. J. WEBER, 1882. NERVOUSNESS, by DR. PAUL JULIUS MÖBIUS, of Leipzig. 8vo, pp. 191.

THIS little work is one of a series of "health-books," and is avowedly written for the laity. The author has, therefore, very judiciously devoted over half the book to the causes of nervousness, the remainder being divided between symptoms and treatment.

Nervousness is not defined except figuratively. It is, says Möbius, the plastic clay out of which the more pronounced neuroses are formed. The chapters on etiology are excellent, and cannot but strike the attention of the non-medical readers. The book, indeed, takes up a morbid condition, which should before have attracted the attention of sanitarians.

Dr. Möbius draws considerably from Bouchut's "Du Nervosisme" and Beard's "Neurasthenia." He is, however, essentially original and independent in his methods and opinions.

PRACTICAL MEDICAL ANATOMY. A Guide to the Physician in the Study of the Relations of the Viscera to each Other in Health and Disease, and in the Diagnosis of the Medical and Surgical Conditions of the Anatomical Structures of the Head and Trunk. By AMBROSE L. RANNEY, A.M., M.D. Wood's Library of Standard Medical Authors. New York: William Wood & Co. 1882.

DR. RANNEY'S object is to present anatomy in an interesting and practical way. He does this by taking up different regions of the body or organs, and describing them, giving at the same time all the points of medical or surgical interest connected therewith. The anatomical descriptions are neither minute nor complete, but so much is given as is thought necessary. There is no question that the author has managed to give a great deal of anatomy in an attractive manner. The book will supplement the regular anatomical studies of the student, and the practitioner can read it with much profit and less weariness than attaches to ordinary works.

In some parts of the work the author shows himself an industrious but superficial gleaner, rather than a sound student. This is notably the case in his description of the skull, which is very imperfect in its anthropological statements.

The illustrations are very poor, especially some of those which aim to illustrate the physiognomy of disease, and which, if inserted at all, should have an artistic value. In the cut illustrating the arteries of the brain, the "inferior temporal lobule," whatever that may be, is placed just below the interparietal fissure. A diagram, later on, showing the arterial circulation at the base of the brain, is attributed to Charcot, when it was in fact drawn by the translator of his work, Dr. E. P. Fowler.

These are, of course, minor errors. It is impossible to deny to Dr. Ranney the credit of having written the most attractive anatomical work extant of a, so to speak, popular character.

Reports of Societies.

BRITISH MEDICAL ASSOCIATION.

Fiftieth Annual Meeting, held in Worcester, England, August 8, 9, 10, 11 *and* 12, 1882.

(Special report for THE MEDICAL RECORD.)

GENERAL SESSION—FIRST DAY, AUGUST 8TH.

THE meeting was called to order at 8 A. M., in the Guildhall, Worcester, by BENJ. BARROW, ESQ., retiring president, who introduced the president-elect, W. STRANGE, M.D., of Worcester.

A vote of thanks was tendered to MR. BARROW for the manner in which he had filled the office of president the preceding year, after which DR. STRANGE delivered his address.

THE ADDRESS OF THE PRESIDENT.

After a few preliminary remarks, he asked the attention of the members to some thoughts "upon the progress of medical science, so-called, and its relation to the advancement of science in general." He divided his subject into two parts, first, that referring to the "revival of medicine," and secondly, that relating to the "survival of medicine." The era of the revival of medicine dated back to the year 1831, when the British Association for the Advancement of Science was organized, and when, a year later, the British Medical Association was founded, and when the profession were prepared to receive new truths, to accept new doctrines and to overthrow old and long cherished dogmas, led by such men as Phillip, Lawrence, Abernethy, Cooper, Latham, Marshall Hall, Brodie, Watson, Graves, Andral, Stokes, and Colles. No deductions were drawn by these men from a few meagre facts, warped and manipulated to fit them to a preconceived theory; but the true Baconian system was honestly adopted and no conclusions come to but such as were justified by the data at command." The time was ripe for a new departure in medical as in other departments of research, the way was open for the freest possible interchange of thought and opinion upon matters requiring discussion, and the British Medical Association stepped in to do its grand work of associating the efforts of the leading medical minds of the day.

Another event, almost coeval with the founding of the Association, came to the rescue and helped to make the decade 1830–40 for ever memorable in the annals of British medical literature. This was the establishment of the *Lancet* as the leading medical journal. Through its agency monopolies were destroyed; hole and corner meetings and doings of the corporations for the benefit of the few to the detriment and exclusion of the many were exposed; pompous ignorance and overbearing imbecility were held up to scorn; the oppressed and obscure, but honest and industrious seeker after truth was brought to the front. After a time, feeling its growing strength, this brave journal attacked the legislature itself. And it was time. Its apathy toward all that concerned the interests of our profession, displayed in its intolerance of the most abominable abuses and monopolies in high places; its utter neglect of the public health; the farce of the coroners' courts; its winking at the atrocious adulterations of the people's food; its inhuman neglect of the sick poor; and its disregard of all decency in respect of the burial of the dead—these abuses were one by one attacked, and their authors and abettors lashed with a pitiless and unsparing hand, until redress and reform were grudgingly conceded. The man who—whatever his faults, and they were many—spent the best part of his life in compelling the legislature to listen to his exposure and his complaints of these gigantic evils, and to redress them, was at length listened to, admitted into the legislature itself, became a politician, and spoiled! "None the less does the memory of Thomas Wakley deserve this testimony from us, who now possess an organ of our own quite capable of maintaining those rights and privileges for which, in the early days our association, we had no sufficient weapon wherewith to do battle."

Then came the *Review*, with its candid and intelligent analysis of medical thought, its fair play to all, and its noble encouragement of everything that was good and true in medicine.

But everything was not due to these influences and to the great names of 1830–40. Those musty old tomes, reposing so peacefully on the back shelves of our libraries, what testimony did they not bear to the self-denying spirit displayed by their authors in transcribing and compiling whole systems of medicine, gathered with a labor and amid difficulties unknown to us, from every accessible source, for the benefit of those who should come after them. Contrast *their* labors with those of our modern medical *dilettanti*, whose hasty and sometimes crude lucubrations are carried weekly by a free press into thousands of medical homes, and say if, in this imperfect sketch of the history of a half century's literature, these older fathers of the *ars medicinæ* should have been altogether passed over and forgotten?

Looking upon the evolution of the medical mind as a continuous process, coming from whence we started, and going we know not whither, he glanced in the second part of his discourse to present prospects of medicine. The surest signs of progress and the best promises for the future were centred in the love of liberty of thought, "freedom to speak, freedom to write, freedom to teach. . . .

"There is no theory which we may not promulgate; no practice, short of manslaughter, which we may not pursue. An unfettered press and open criticism are the courts before which all claims to new discovery, to improved practice, to advance in knowledge must be brought. All must stand or fall by their own merits. Still, great names have their weight. The words of a Jenner or a Paget, compared with those of little-known authors, are as the discharge of an eighty-ton gun compared with that of a pocket-pistol. Now the great value of this liberty, and the free organs which it has set up, must be evident to all. Its advantages in regard of freedom of debate, of teaching and of writing, are too great ever to be allowed to be withdrawn from us under any circumstances whatever. For by it original genius obtains an immediate and impartial hearing; by it the patient and self-denying laborers of industry and talent, who may have passed years in silent research, at length obtain their reward. Let us, then, never relinquish into the hands of the State the decision as to what shall be the kind and amount of our knowledge on entering our profession, or in what way and under what restrictions we shall conduct our experiments and inquiries into the laws of nature for the good of mankind; or in what manner and for what reward we shall carry our knowledge to the bedsides of our patients, be they

the rich in their mansions or the poor in our hospitals; or in what way we shall regulate our mutual intercourse. Over the church and over the law, for obvious reasons, it may be desirable that the State should hold a check; but over the investigations of science, and over the application to practice of that science, we will have no master other than the moral conscience of our profession itself."

The speaker next alluded to the growing philanthropy of the profession as the second factor in the line of its progression, and lastly to its love for truth in prosecuting its researches, giving numerous examples of the latter.

REPORT OF THE COUNCIL.

Mr. Fowke presented the regular report of the Council, which referred to matters of interest to the Association merely.

SHALL HOMŒOPATHS BE EXPELLED FROM THE ASSOCIATION?

Mr. Nelson Hardy, of London, in moving the adoption of the report, proposed the following as an amendment to the same: "That the report of the Council, together with the financial statement for the year ending December 31, 1881, be approved, adopted, and entered on the minutes; and that it be an instruction to the Committee of Council that the avowal of the profession of homœopathy, or any other designation implying a special mode of treatment, shall, *ipso facto*, disqualify from membership of the British Medical Association."

After a lengthy discussion the amendment was put and was rejected by a large majority.

CONCERNING THE ELECTION OF THE EDITOR OF THE BRITISH MEDICAL JOURNAL.

Dr. Milner Fothergill, who had given notice of a motion concerning the election of editor of the *British Medical Journal*, was absent when that order of business was reached. Dr. Fothergill had asked by letter that the subject be postponed to another time than that fixed by the Council. It was accordingly allowed to go by default.

Dr. Ward Cousins (Southsea) proposed alterations in the by-laws affecting the *Journal* and Finance Committee. These were, after considerable debate, referred to the Council, after which the meeting adjourned.

Second Day—Wednesday, August 9th.

The meeting was called to order by the President, Dr. Strange.

Dr. Fothergill desired to bring up his resolutions regarding the election of editor of the *Journal*, but he was ruled out of order.

ADDRESS IN MEDICINE.

Dr. W. F. Wade, of Birmingham, then delivered the Address in Medicine.

The speaker began by calling attention to the therapeutical methods in use half a century ago. As we can be helped to write and speak correctly by studying a dead language, so, he thought, we can learn much by studying therapeutical methods now entirely abandoned. The great characteristic of the therapeutics half a century previous was blood-letting. It was difficult to find a disease in which high authority did not advocate this practice. A revolution in opinion, however, was soon to take place. It was a time, when there was a general overturning of old systems, and the medical profession was affected by the general tide of thought and feeling. The importance of the *vis medicatrix naturæ* was being recognized.

The speaker referred to the tenacity with which the practice of blood-letting was adhered to. There existed a blind credulity in the dictates of an imperfect science. This imperfectness of medical science was at last felt. It should always be borne in mind now. The physician deals with a science of probabilities. But this science is not a contemptible one. The existence of the Deity is attested by it alone, according to some philosophers.

With these facts in mind, caution in the use of drugs is needed. We are often tempted to give powerful drugs when we really cannot say why they are indicated. The case is distressing and needs, as we think, some active measure. It should be borne in mind that meddlesome medicine is as bad as meddlesome midwifery or meddlesome surgery.

Dr. Wade then gave a brief history of Marshall Hall's fight against blood-letting and his final triumph. The speaker also showed how Hall's vivisection experiments were so abundantly justified by their results. He also referred to Harvey's experiments, and defended Harvey's claim as discoverer of the circulation.

The speaker, although admitting the imperfection of medical science, dilated upon the fact that it was most progressive, and this not only in the matter of new drugs but in our knowledge of how better to use old ones.

The desire for advance, for something new, tempts us to accept errors, and especially to make hasty generalizations. The use of large doses of digitalis, and Todd's theory of the universal applicability of alcohol were instanced as examples of such errors.

The search for specifics had tempted many. One reason why this search was likely to mislead lay in the fact that it almost inevitably involves a conception of disease as a unity, instead of a complexity of processes.

The speaker directed attention to another danger into which the modern therapeutist may be led. It is a very prevalent opinion that "debility" is a predisposing cause of disease, and the notion of debility has now become so large that the condition itself is often confounded with disease. The therapeutical method of building up the system rather than attacking the disease is therefore very prevalent. Yet in some cases this is undoubtedly wrong. A disease may seize upon a debilitated body and run a lighter course than if the person were robust. We must attack the disease, therefore, if possible, as well as strengthen the nutrition.

The speaker, in concluding, said that he had presented various past therapeutical errors in order that we might learn from them. Dispassionate survey of present medical practice forced him to the conclusion that on a very large scale, and in both chronic disorder and organic disease, the physiological basis of treatment is too often unduly subordinated to the restorative basis of treatment. And the greater our advances in anatomy, physiology, and pathology, the more need that our powers of observation be sharpened, refined, and sensitized; for sources of error multiply with increase of knowledge.

At the conclusion of the address a vote of thanks was tendered to Dr. Wade.

COMMITTEE OF THE COUNCIL.

The following members were then reported as elected by the Council to serve on the Committee of the Council: J. T. Arlidge, M.D.; J. H. Bartlett, M.B.; J. P. H. Boileau, M.D.; L. Borchardt, M.D.; B. Foster, M.B.; E. Long Fox, M.D.; A. J. Harrison, M.B.; C. Holman, M.D.; Leslie H. Jones, M.D.; H. Lanchester, M.D.; C. Macnamara, Esq.; F. E. Manby, Esq.; Frederick Mason, Esq.; R. H. B. Nicholson, Esq.; Rushton Parker, Esq.; S. W. Sibley, Esq.; E. H. Sieveking, M.D.; A. P. Stewart, M.D.; T. Sympson, Esq., and John Wood, Esq.

THE NEXT MEETING IN LIVERPOOL.

An invitation was received from the profession in Liverpool to hold the next annual meeting of the Association in that place. This was unanimously accepted, and Dr. A. T. H. Waters, of Liverpool, was chosen as the next President.

An invitation to hold the meeting for 1884 in Belfast was also received, but its consideration was postponed for a year.

The Association then adjourned.

PRESENTATION OF THE BUST OF SIR CHARLES HASTINGS, FOUNDER OF THE ASSOCIATION.

At 1.30 P.M. the members were entertained at luncheon by the Worcester and Hereford Branch, when a bust of Sir Charles Hastings, the founder of the Association, was presented to the city of Worcester. Speeches were made by Dr. Strange, Mr. George Hastings, M.P., Mr. Husband, and the Mayor of Worcester. About five hundred members were present.

THIRD DAY—THURSDAY, AUGUST 10TH.

The meeting was called to order at 10 A.M. by the President, DR. STRANGE.

THE ADDRESS IN SURGERY

was delivered by WILLIAM STOKES, F.R.C.S.E., of Dublin. After a few introductory remarks, in which the speaker referred to the general work of the profession and the efforts to raise the standard of education, he passed to the enumeration of some of the chief advances which had been made in surgery during the last half century and then to the contemplation of those in which he had been more especially interested. These were the abandonment of indiscriminate blood-letting, the reckless use of mercury, and the use of the seton and moxa; the introduction of the pressure treatment of aneurism, of drainage in the treatment of wounds and abscesses, of metallic sutures; the perfecting the operations for vesico-vaginal fistula by Sims and others; lithotrity; the treatment of stricture; joint resections; the placing of ovariotomy upon a firm basis by McDowell, Clay, and Wells; gastrotomy; excision of the pylorus, spleen, kidney; supra-pubic removal of the uterus; laparotomy; cholecystotomy; improvements in the methods of amputation; bloodless surgery; skin-grafting, sponge-grafting, torsion; cure of aneurism by arterial ligation; treatment of fracture by improved splints; manipulation in the treatment of luxation, and improvement in the treatment of spinal disease by the use of the plaster jacket by Sayre. But great as had been the advance in all these directions, they paled before three which had not been mentioned, namely, (1) the discovery of the means of banishing pain; (2) the means of bringing about the restoration of an injured joint, so as to obviate the necessity of excision; and (3) the enunciation of the principle and establishing of the practice by Pasteur and Lister of antisepticism: *anæsthetics*, *antiseptics*, *osteogenesis*. These were the topics to which he directed special attention.

ANÆSTHETICS.

Whatever anæsthetic was employed, even with the most careful use and precaution, the gauntlet of peril was to be run, and he believed it would always be so. Of ether and chloroform much had been done to diminish the danger attending their use, such as the avoidance of ether in infancy and extreme age, and in cases where there was reason to believe that chronic renal disease existed; the avoidance of chloroform in all cases of cardiac disease, and the constant bearing in mind its liability to produce cardiac paralysis.

Again, the administration of anæsthetics should be entrusted only to persons of experience. In the majority of cases he unhesitatingly would use ether, and some one of the apparatuses in which *air was rebreathed*, should *always* be employed. To Morton, of the Massachusetts General Hospital, was given the credit of first demonstrating, in 1846, the anæsthetic properties of ether; and to Simpson, of Edinburgh, the anæsthetic properties of chloroform for surgical operations, and all must agree with Dr. Gross, of Philadelphia, in the statement that, if America had never discovered anything else, the world owed her a debt of everlasting gratitude.

ANTISEPTICISM.

The treatment of wounds was the corner-stone of surgery, and the antiseptic practice should rank as the greatest advance which had been made during the last half century.

Special attention was then directed to Mr. Savory's address before the association at Cork two years ago. In that address, when stripped of its eloquence, two facts came to view: (1) the admission of the germ theory of putrefaction; and (2) that the dressings which Mr. Savory advocated as superior to those recommended by Mr. Lister, were in themselves antiseptic, consisting of carbolized oil and sutures, drainage, washing the wound with a solution of permanganate of potash or other antiseptic.

With regard to Mr. Lister's remarks, he did not "enter antiseptic surgery and then sing a dirge over it."

From a purely practical point of view it appeared to be of but little consequence whether we adopted the view that the micro-organisms were mischief-makers or mischief-carriers; that is, whether they operated primarily or secondarily. From this point Dr. Stokes discussed at some length the theories and the tests concerning the value of antiseptics, and said that he did not consider ovariotomy as the touchstone with regard to their value. Bloody serum he believed to be the most unfavorable ground for the development of the germs. Resection of the knee-joint was the best test, and several cases were cited.

With regard to this operation, and all others in which antiseptics were employed, the important question to be asked was, Could these results have been obtained previous to Lister's teachings of antiseptic surgery? To this question there was but one answer, and that was, Impossible.

Dr. Stokes then gave some of his personal experiences in the use of the antiseptic treatment under unfavorable hygienic surroundings, in connection

with public institutions in Dublin, especially the Richmond Hospital. In six years hospital gangrene had disappeared, and not a single case of erysipelas, septicæmia, or pyæmia had occurred when the Listerism had been *accurately carried out*. Of six hundred cases in this hospital only a mortality of three had occurred, and in not a single case had death taken place where Listerism was accurately employed, and the cases were those of compound fracture, abscesses, ununited fractures, foreign bodies in joints, etc., etc.

It had been a subject of profound regret to him that so many surgeons of deserved celebrity had been found disposed to either discard Listerism altogether, or to give it only a lukewarm acceptance.

Dr. Stokes then directed attention to

OSTEOGENESIS,

upon which he spoke at some length, reviewing various operations, such as Carden's, Gritti's, and the modifications and improvements which had been made in sub-periosteal surgery. The principle of the long anterior flap in amputation at the knee received a special compliment.

The address was closed with an eloquent reference to the subject of *vivisection*.

On motion of MR. PRIDGIN TEALE, seconded by SIR WM. MACCORMAC, the Association gave a vote of thanks to Mr. Stokes for his able and eloquent address.

THE PRESIDENT then presented the

STEWART PRIZE OF FIFTY GUINEAS,

which had been awarded to Surgeon-Major HENRY VANDYKE CARTER, M.D., I.M.D., for a dissertation on "Spirillum, or Relapsing Fever."

The prize was received by the Surgeon-General in behalf of Mr. Carter.

The Association then adjourned.

SECTION IN SURGERY.

AUGUSTIN PRICHARD, F.R.C.S., President.

EARLY OPERATIVE TREATMENT OF JOINT DISEASE AS A PREVENTIVE OF EXCISION.

Discussion on the above subject was opened by MR. J. GREIG SMITH, who said that the principle which he wished to advocate was what might be called, "tinkering of the joint *vs.* excision." Scrape away diseased tissues, move the joint freely, drain antiseptically, but do not drain too long. Deal as freely and as vigorously as possible with the synovial membrane and remove diseased bone bodily.

The discussion was continued by MR. PRIDGIN TEALE, of Leeds, who thought that treatment of joint disease had been based far too much upon what had been seen in hospitals, where, as a rule, the cases were admitted only when the disease had become much advanced. The antecedent conditions had been too much neglected, and the great question was, "How can we best deal with the elementary processes?" Except in the matter of rest and counter-irritation, practically but little had been done. For several years he had attempted to deal surgically with the earlier processes, and the point which he had in view was this. There were certain early conditions, exactly what they were he was not yet prepared to say, where there was tension within the joint, attended with pain, and if the tension could be removed the pain would be relieved and, in many instances at least, the disease would be arrested. His plan of treatment had been to make subcutaneous incisions one-fourth of an inch in length into the capsule of the joint and allow the fluid to escape into the surrounding tissues to be absorbed. He then cited several cases of incipient hip-joint disease in which he had adopted this method with success.

MR. BARWELL, of London, said that he had practised, and already published in his work on joint diseases, the method recommended by Mr. Teale. He had also used the aspirator instead of the knife, but had found that it sometimes disappoints, especially if the fluid within the joint was pus. When pus was found, he at once introduced a tenotomy knife, divided the capsule freely and left the opening in the skin as a mere puncture.

MR. LUND had known of cases of hip-joint disease where great relief followed puncture. He had also known of two cases in which abscess followed the operation. He wished, however, to confirm Mr. Teale's remarks, and added the abscess cases simply to show that unpleasant results might attend the method.

A MEMBER directed attention to the use of Martin's elastic bandage, presented by Dr. Marcy, of Boston, at the International Medical Congress, in the early treatment of joint affections. He regarded it as worthy of a trial.

MR. H. MORRIS, of London, spoke of the great advantage of aspiration in acute cases with pain and tension. In those cases where pus was found, free incision should be made, followed by position and rest. But there was a class of cases in which the treatment recommended by Mr. Smith was of service. He then referred to two cases, one of the hip and the other of the shoulder, in which a small sequestrum was found that doubtless kept up the irritation and suppuration, and which, if it had been removed, the patient's life, perhaps, would have been saved.

MR. WILLIAM THOMSON then read a paper on

RUPTURE OF THE KNEE-JOINT AND COMPOUND FRACTURE OF THE PATELLA.

The paper consisted of the report of a case, with remarks. It was one in which he practised suturing of the bone with silver-wire, afterward excised it, and the patient recovered. The operation of cutting down and wiring the fragments together was first performed by Dr. Crocker, of San Francisco. Mr. Thomson, however, thought it should not be done in ordinary recent cases, and questioned as to whether it was a justifiable operation. In old cases it might be justifiable. He had never seen a patient who had ligamentous union, and was unable to use the limb, and he did not regard ligamentous union as one possessing special disadvantages. Indeed, he had never seen a case of osseous union in the living human subject.

MR. JESSOP, of Leeds, referred to two cases of fracture of the patella. The first was compound, with extensive laceration of the soft parts. The wound was thoroughly cleansed, treated antiseptically, the fragments wired together; not a single unfavorable symptom developed, and the result was bony union with good motion in the joint.

The second case was one of simple fracture of the patella, which he made compound, cleansed away the blood, treated it in the same manner as he did the first case and with the same happy result.

MR. WHEELHOUSE, of Leeds, related a case of compound fracture of the knee-joint, treated in the same

manner described by Mr. Jessop, and at the end of two months the patient left the hospital with firm bony union and a flexible joint.

He had also had a case of old fracture of the patella in which there was long ligamentous union, and the patient could scarcely use the limb. He opened the joint as freely as was the one with compound fracture from injury opened, removed all the fibrous union, revivified the edges, applied wire sutures to the fragments, and the man recovered with ability to walk and work as well he ever had done.

Dr. Moore, of Belfast, had removed the blood from the joint by means of the aspirator, in cases of fracture of the patella, and with good results.

Mr. Teale had had one case of bad union after fracture of the patella, the fragments being separated to the distance of an inch and a half. He performed the operation spoken of by Mr. Wheelhouse, and found great difficulty in bringing the fragments together, but they were finally easily approximated by means of Malgaigne's hooks, secured with wire sutures, and a good result was obtained.

So far as simple fracture was concerned, he had reached the point of *not* applying any apparatus whatever, but simply treating the limb by position.

LITHOLAPAXY.

Mr. Reginald Harrison, of Liverpool, reported a case of stone in the bladder removed by Bigelow's method. The calculus weighed two and one-half ounces, was composed of phosphates and urates. The operation lasted two hours and ten minutes. Thirty washings were made, and the entire stone was removed except a small fragment which passed by the urethra. The patient recovered without the development of an unpleasant symptom. A smooth-bladed lithotrite was used, and it was the instrument he recommended. He had not experienced any difficulty in its use on account of impaction. He employed Bigelow's original washing apparatus.

Mr. Gold presented a photograph of a calculus removed by Bigelow, which weighed three ounces. [See proceedings of the New York Academy of Medicine, Medical Record, vol. xxi., p. 578.]

Mr. J. Ward Cousins exhibited

A LONG-BEAKED STAFF FOR LITHOTOMY,

and claimed for it the following advantages: 1st, the angle of the instrument could always be reached, and thus the operator could always know where his finger and knife were; 2d, it obviated the danger of pushing the bladder off from the beak of the instrument; and 3d, it enabled the operator to raise the base of the bladder up beyond the pubes and thus obviate the danger of injuring the rectum.

He had never had any difficulty in introducing it, nor had he ever wounded the posterior wall of the bladder with it, and did not believe that, if properly used, any inconvenience would be experienced in those directions.

Mr. Browne referred to a case where, by ordinary lateral lithotomy, a calculus weighing seven and one-half ounces was removed and the patient recovered without difficulty.

He objected to the long-beaked staff, because of its apparent difficulty of introduction.

The discussion was continued by several members, but no essentially new points were developed.

A discussion on

BONE-SETTING.

was opened by Mr. Howard Marsh, of London, and continued by Mr. Cross. It consisted chiefly of a narration of cases in which bone-setters had either succeeded or made disastrous failures, and an effort was made to explain why success attended their manipulations in certain apparently remarkable instances. The first paper was really one on "manipulation as a surgical treatment," under the heading of "Bone-Setting."

Mr. Wm. Adams, of London, then read a paper on

THE SELECTION OF CASES FOR FORCIBLE MOVEMENT IN THE TREATMENT OF STIFF JOINTS, AND THE METHOD OF PROCEDURE.

The selection of cases could be based only upon accurate pathological considerations. But the basis, to a great extent, was still undetermined. By the term stiff joint, he meant to include cases of bony or fibrous anchylosis, properly so called. The essential cases are those in which joints are made stiff by inflammatory thickenings external to the joint, including capsule and ligaments, and inflammatory adhesions between the articular cartilages. The existence of articular cartilages was essential to the restoration of healthy motion.

Cases of stiff joint were classified as follows:

First.—Those of traumatic origin in healthy constitutions, generally in adults.

Second.—Those due to rheumatic inflammation of the joint.

Third.—Those due to strumous disease of the joint.

Fourth.—Those following acute suppurative inflammation, of pyæmic origin in the neighborhood of the joint and extending into it.

Fifth.—Those due to muscular contraction.

The *first* class of cases were generally favorable for treatment by forcible movement, and they could be divided into *four* groups:

a. Cases occurring after dislocations which had been reduced.

b. Cases in which motion was limited in non-reduced dislocations of long standing. It was sometimes advisable in these cases to resort to forcible movement.

c. Cases occurring after fracture into, or in the neighborhood of joints.

d. Cases of stiff-joint after bruises, followed by inflammation of the joint.

The *second* class of cases were usually favorable for treatment. In rheumatic inflammation, whether affecting the joints or not, or the pericardium, it might be stated, as a general rule, that there was no disposition either to suppuration or ulceration, the usual result being effusion of lymph and organizations of adhesions. The cases could be divided into *three* groups:

a. Cases of stiff joint occurring after acute rheumatic inflammation.

b. Cases occurring after gonorrhœal rheumatism, generally favorable for treatment.

c. Cases occurring after chronic rheumatic inflammation, generally favorable for treatment when attempts to regain motion have not been too long delayed.

The *third* class of cases were essentially unfavorable for treatment, in consequence of the destructive character of the disease. Even when external abscess did not occur, disorganization of the joint was usually complete, and fibrous or bony anchylosis was the best result to be expected.

The *fourth* class of cases were essentially unfavorable for treatment, in consequence of destruction of

the articular cartilages and disorganization of the joint.

The *fifth* class of cases occurred, for the most part, in connection with disease of the hip- and knee-joints, and forcible movement was totally inapplicable. Gradual extension only should be used.

With regard to *the mode of procedure:* When it was necessary to use a great amount of force, permanent motion probably would not be obtained. Besides, there were several accidents, such as fracture, rupture of blood-vessels, etc., which were liable to occur. Instead of employing the violent method in such cases, and attempting to obtain full range of motion, he adopted the gradual method, using at first only sufficient force to obtain the least possible movement, and gradually increasing the range of motion until the full extent was obtained.

After the operation he applied some such dressing as spongio-piline, and secured absolute rest. A weight and extension might be used in some cases. Absolute rest and local vapor-bath. By the gradual method pain and inflammation were avoided.

In the simpler forms a single operation would frequently suffice; but it might be necessary to repeat the operation many times. He referred to a case in which eighteen operations were performed, with the result of obtaining full and voluntary motion.

SECTION IN MEDICINE.

Dr. Clifford Allbutt, M.D., F.R.S., President, delivered his opening address, the chief merit of which was its excellence as a literary production. It was well adapted to the jubilee meeting, and was retrospective in character.

The first paper was read by Dr. Fletcher Little, London, and entitled,

DEMONSTRATION OF MEDICAL RUBBING.

It was a demonstration upon a patient of the various methods of rubbing, with a detailed statement of the points to be observed in its application. It was a combination of ordinary skin friction, French massage, and medical calisthenics of Zander, London. The principle was to relax every part to be rubbed in the most careful manner, and Dr. Weir Mitchell's book will give an excellent idea as to how it is to be done.

Dr. W. S. Playfair then opened a discussion on

THE SYSTEMATIC TREATMENT OF AGGRAVATED HYSTERIA AND ALLIED FORMS OF NEURASTHENIC DISEASE.

It was a *résumé* of Dr. Weir Mitchell's method of treatment which he had had carried out successfully in the treatment of a class of cases which he had heretofore looked upon as the opprobrium of medicine.

Dr. Balfour, of Edinburgh, opened a discussion on

CHLOROTIC MURMURS,

in which he laid special stress upon the importance of promptly removing them by systematic constitutional treatment, lest they become evidence of permanent cardiac damage.

Dr. Austin Flint, of New York, read a paper on

THE SELF-LIMITED DURATION OF PULMONARY DISEASE,

which was followed by a paper on

THE CONTAGION OF PHTHISIS,

by Dr. C. T. Williams, of London.

A general discussion of the subject of phthisis then followed, and was participated in by the President, Drs. Bennett, Drysdale, and others.

Dr. Henry Bennett, of London, thought it possible that the impure air surrounding a phthisical patient, coming from the expectoration, sweats, etc., might, if confined, give rise to something like contagion.

With regard to the spontaneous cure of phthisis, he had seen many unmistakable cases, and that phthisis had been recovered from had been proved by the existence of evidence of previous disease at the apices of the lungs found at autopsies.

Dr. Drysdale had long hoped that it was true we were going back, as Dr. Flint had indicated, to speaking of phthisis as pulmonary consumption, and identical, clinically, with pulmonary tuberculosis. Concerning the natural history of phthisis, he thought it could hardly be considered a self-limited disease in the same sense as small-pox, for example, was known to be; but that the affection underwent spontaneous cure was undoubtedly true.

With regard to the contagion of phthisis and its hereditary transmission, he believed, as Dr. Williams had expressed it, that it was incompatible with the theory of germs. He was unable to understand how the germ theory was to help us in the explanation of the transmission of the affection.

The discussion was continued, but nothing essentially different from that already given by Prof. Flint was developed, and with his views the readers of The Record have, from time to time, been made familiar.

Dr. A. J. Harrison, of Clifton, then read a paper on

PRIMARY ENDOCARDITIS,

in which he maintained that it was not only possible, but that it had occurred, and would again occur. The histories of four cases were given.

The President remarked that cardiac disease should not be taken as the test of the severity of rheumatic fever. Endocarditis was not infrequently the first event in rheumatic fever.

It not uncommonly was the only event by which the rheumatic fever manifested itself. He then referred to cases, notably one in which there was a rheumatic and phthisical family history and in which endocarditis occurred without other local manifestation.

Dr. Balfour said that every case of systolic murmur should not be considered as a case of endocarditis, because a certain amount of rheumatism might occur without endocarditis at all, and again, he had not seen a case of rheumatic fever in which there was not a systolic murmur. In fever of all kinds, especially in debilitated patients, a systolic murmur could almost invariably be detected.

Besides, he thought that every case of friction should not be regarded as a case of pericarditis.

Dr. Ashley referred to the fact that he had frequently observed endocardial and pericardial murmurs in connection with slight attacks of tonsillitis, a fact long ago observed, and, as was well known, tonsillitis had a casual connection with rheumatic fever, the same as influenza, already mentioned by the President. He therefore made it a rule to examine carefully in all cases of tonsillitis, especially in children, for endocardial and pericardial murmurs.

Dr. McVail, of Glasgow, then read a paper on

THE INTERRUPTED OR WAVY BREATH-SOUNDS OF PHTHISIS,

in which he gave what he regarded as a more correct explanation of their production than those commonly accepted, namely, roughened pleural surface

or some obstacle to the free entrance of the current of air into the bronchial tubes.

The explanation offered was the following: Ordinarily the heart-sounds are not heard over the right apex in inspiration, that is, with normal lung and heart, but can be heard in expiration. But when the lung becomes consolidated, however slight, it is a better conductor of sound, and the heart-sounds are mingled with the inspiratory sound and give rise to the irregularity, and the interruption is single or multiple according to the rapidity of the heart's action in proportion to the length of the inspiration.

Dr. Williams said that he accepted Dr. McVail's explanation, and that in a book written by his father and himself the same explanation had been given, with the statement that it was original with Theophilus Thomson so far as they had been able to ascertain.

THE TREATMENT OF CARDIAC, HEPATIC, AND RENAL DROPSY.

The discussion was opened by Mr. Leech, who wished to make prominent the fact that disappointment in the action of diuretics arose very frequently from expecting them to do what they were unable to do.

With reference to diaphoretics, he believed that we misjudged of the action of remedies. Because diaphoresis followed the use of a remedy it did not necessarily follow that it was the effect produced by the remedy.

With reference to the use of purgatives, he had not seen the benefit which had frequently been claimed for them. Where he had measured the urine he had not seen benefit follow the use of hydragogues. His general plan was to put the patient in bed, secure rest for some time, and then administer diuretics. When diuretics failed purgatives rarely succeeded. He had not seen benefit follow the use of the hot-air bath. In acute renal dropsy spontaneous diuresis occurred in almost every case. He had entirely failed to see any benefit from the use of pilocarpin.

Tapping was a mechanical measure to be resorted to. Exhaustion after tapping was most marked in ascites from cirrhosis; but it must be borne in mind that there was a marked wasting as one of the phenomena of that affection. He had observed only slight loss of strength after tapping for cardiac dropsy. He had observed peritonitis after tapping in only one case.

Southey's capillary tubes for draining the legs in general anasarca were of great value, although he had seen one case of phlegmonous erysipelas follow their use.

He had found that diuretics would act after rest and good diet, even though they had previously failed.

The President had found diaphoretics to be exceedingly uncertain in the treatment of any form of dropsy. He regarded hydragogues as very useful. The hot-air bath, in his experience, had been unsuccessful. He hesitated to tap the patient's legs, because of the liability to the occurrence of erysipelas; but the operation was almost brilliantly successful, if it could be performed without that liability, in cases of cardiac and renal dropsy.

He had used Southey's tubes with satisfactory results. With regard to tapping, he hesitated to adopt it early or to repeat it, because of the liability to produce exhaustion.

Dr. Thomas had found diaphoretics inactive, but sometimes they were successfully used after purgatives had been given.

He had not found any real benefit following attempts to act upon the skin. He had not resorted to early tapping in ascites.

Dr. Carter had used the hot-air bath and hot drinks with marked benefit, especially in dropsy following scarlatina, and had seen diuresis very frequently follow diaphoresis.

For cardiac and other dropsies other means must be undertaken, and digitalis had, in his hands, proved to be an exceedingly useful remedy.

He had resorted to early tapping, but preferred to use a very small trocar which would allow of only slow removal of the fluid, believing that thereby the liability to exhaustion was considerably reduced.

He referred to three cases of ascites in which different results followed tapping. The *first* was ascites with cirrhosis of the liver, and tapping was followed by gradual exhaustion. The *second* was ascites with Bright's disease, and tappings doubled the quantity of urine, and were always followed by relief. The *third* was ascites with cardiac disease, and each tapping was followed by diminution in the quantity of urine by one-half, although relief was afforded. This patient was tapped seventeen times. The patient with cirrhosis died, and the other two left the hospital in a comparatively comfortable condition.

He had used Southey's tubes for the legs with good results. He believed that the constant use of hydragogues should not be adopted; at intervals some simple cathartic should be used. The combination of rhubarb, jalap, etc., with elaterium, he regarded as very advantageous.

Dr. Roden recommended iodide of potash combined with full doses of nitric acid. Some preparation of iron with saline cathartics possessed special advantages.

Dr. Phillips had used Southey's tubes successfully, but regarded hypodermic injections of pilocarpin as one of the most valuable agents that could be used.

SECTION IN OBSTETRIC MEDICINE.

Dr. William Leishman, President.

Dr. Arthur W. Edis, Vice-President, in the Chair.

A discussion on

SUBINVOLUTION OF THE UTERUS, ITS CAUSES, ITS RELATION TO UTERINE DISEASE, AND ITS PREVENTIVE TREATMENT,

was opened by Dr. John Williams, of London, who first defined involution as a process of fatty degeneration which began in the uterus about the fourth day after labor—not later than the eighth—and was completed in about four weeks; a process by which the organ was restored to its natural condition. Clinically, involution consisted in the reduction of the volume of the puerperal uterus to the size of the unimpregnated organ.

Reference was then made to the various ways of measuring the organ after parturition. Concerning Sinclair's method by catheterization, he thought it liable to serious errors during the first ten days following delivery.

After the uterus had sunk into the pelvis, bimanual manipulation combined with catheterization was the only method which gave reliable results.

The average period at which he had found the fundus within the pelvis was the twelfth day, and he assumed, for the purposes of his paper, that the uterus has undergone normal involution on the twelfth day, although the assumption would lead to some errors, because the settling of the organ into the pelvis was not positive evidence of the non-existence of subinvolution.

THE CAUSES OF SUBINVOLUTION

had been said to be general debility, advanced age (bearing children late in menstrual life), multipara, premature delivery, protracted labor, post-partum hemorrhage, retention of portions of the placenta and membranes, laceration of the perineum, bruising and laceration of the cervix uteri, pelvic inflammation, too early exertion or over-exertion, displacements of the uterus, and non-suckling. General weakness must be expected to exert an influence.

Multiparity had been said to cause subinvolution, but observation seemed to show otherwise. Premature labor had come under his observation too infrequently to enable him to draw any conclusion.

The effect of protracted labor had been differently estimated by different observers.

Lacerations of the perineum played an important part as a cause of subinvolution.

It did not appear from his analysis of one hundred and twenty-six cases that laceration of the cervix affected the process of subinvolution.

Pelvic inflammation retarded involution.

Too early exertion had been maintained, with good reason, as a cause of subinvolution. Special reference was then made to the views of Dr. Goodell, of Philadelphia, who advocated getting the patient out of bed on the fourth or fifth day. Dr. Williams had not ventured to follow the method, and, therefore, had no data upon it. The opposite method, however, had been used, and with equally satisfactory results, and with the avoidance, as it seemed to him, of serious dangers.

The influence of nursing had been usually held to be highly favorable to involution.

In making a *résumé* of the causes, Dr. Williams put down general debility (?), multiparity, and advanced age (?), post-partum hemorrhage, retention of portions of placenta and membranes, laceration of the perineum, and pelvic inflammations.

The *results* of subinvolution were hemorrhage, dysmenorrhœa, prolapsus.

The *treatment* consisted in the removal or prevention of the cause. Some were not removable, but post-partum hemorrhage, laceration of the perineum, pelvic inflammations, and retention of portions of the placenta and membranes could, in a great degree, be removed or prevented. Wounds of the perineum should be closed *at once*.

He did not think that *uterine* drainage was improved by the sitting posture, although drainage of the vagina was made better by it. The removal, however, of the discharges from the uterus and vagina was one of the chief questions in the treatment of the puerperal state. Vaginal injections should be commenced immediately after delivery, and repeated twice daily, at least, and should be abundant, hot, and contain a disinfectant. They should be abundant to insure absolute cleanliness, and the temperature should be 100° to 115° F. *Prevention* meant three things: (1) emptying the uterus, (2) securing a well contracted uterus, and (3) absence of fever. No better means for securing the second and third objects could be employed than hot disinfectant vaginal injections and closing wounds of the perineum.

Dr. W. S. Playfair thought that subinvolution was known by its effects rather than by the actual existence of anything which could be readily determined by physical examination. A very large proportion might have a subinvoluted uterus, but it was only when it was associated with other conditions that it was discovered. He was certain that in private practice subinvolution was not detected except by the morbid phenomena to which it had given rise.

Many of the causes mentioned were undoubtedly causes of subinvolution. But he was surprised to hear that traumatic injuries of the uterus had not led to subinvolution in Dr. Williams' experience. It was difficult to understand how laceration of the perineum should, in a large proportion of cases, give rise to subinvolution when not properly treated, and that laceration of the cervix itself should not produce that effect. Nor was it at all consistent with his experience, for he was satisfied that in a large proportion of cases there did exist more or less marked laceration of the cervix, and that this was an accompaniment, if not a cause, of inflammatory conditions about the uterus and subinvolution.

He thought Dr. Williams had done Dr. Goodell slight injustice by saying that he disapproved of rest after delivery; for his understanding of Dr. Goodell's paper was that he recommended, after delivery, to place the woman in the erect posture early for the express purpose of securing drainage of the vagina; and the posture was to be supplemented by vaginal washings.

Dr. Playfair was, however, greatly impressed with the importance of rest in the treatment of the puerperal condition, and he did not allow his lying-in patients to get up until ten or twelve days after delivery, and then to lie upon a sofa. He was equally certain with Dr. Goodell that the temporary use of the semi-erect posture, as sitting to pass water twenty-four or forty-eight hours after delivery, was an effective means of enabling the vagina to be thoroughly drained. That, of course, was upon the supposition the patient was otherwise perfectly healthy.

Dr. Henry Bennett said that there was nothing contrary to his experience in Dr. Williams' paper, if the discussion was restricted to the condition of the woman during the first two months after delivery. But if it did not involute, what occurred after the second month? This was an important question, and he discussed at some length the relations between subinvolution and chronic inflammation of the uterus and its surrounding tissues.

The discussion was continued at some length, but no new points were brought out. It was merely an expression of difference of opinion concerning a few points already presented, sustained, perhaps, by the history of one or two cases.

Ovariotomy at Fifteen Years of Age.—A girl, aged fifteen, had suffered for several years with a tumor in the left iliac region, which reached enormous proportions. She had been tapped four times, was very weak and emaciated. On operating, the cyst was found extensively adherent to the liver, stomach, walls of abdomen, etc. The tumor and contents weighed fifty-nine pounds. Recovery rapid and complete.—*Med. Bulletin.*

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 14, 1882, *to August* 19, 1882.

BILLINGS, JOHN S., Major and Surgeon. By direction of the President, relieved from duty as a member of the National Board of Health. S. O. 190, A. G. O., August 17, 1882.

BROWN, J. M., Major and Surgeon. Assigned as Attending Surgeon at Headquarters Department of the South in addition to his duties as Post Surgeon at Newport Barracks, Ky. S. O. 79, Department of the South, August 10, 1882.

HUBBARD, V. B., Major and Surgeon. Now awaiting orders, to report in person to the Commanding-General, Department of the Missouri, for assignment to duty. S. O. 186, A. G. O., August 11, 1882.

SMART, CHAS., Major and Surgon. By direction of the President, detailed as a member of the National Board of Health, organized under act approved March 3, 1879, vice Major Billings, surgeon, relieved. S. O. 190, C. S., A. G. O.

BYRNE, CHAS. B., Captain and Assistant Surgeon. The leave of absence granted him in S. O. 68, July 12, 1882, Department of the South, is extended two months. S. O. 189, A. G. O., August 11, 1882.

SEMIG, B. G., Captain and Assistant Surgeon. To be relieved from duty in Department of the Platte, and on expiration of his leave of absence on surgeon's certificate of disability granted him in S. O. 121, C. S., A. G. O., to report by letter to the Surgeon-General. S. O. 186, C. S., A. G. O.

WILCOX, T. E., Captain and Assistant Surgeon. To accompany Troop F, 1st Cavalry, to Fort Walla Walla, and then repair to these Headquarters for assignment to duty at Vancouver Barracks. S. O. 106, Department of the Columbia, July 31, 1882.

TAYLOR, M. E., Captain and Assistant Surgeon. Relieved from duty at Jefferson Barracks, Mo., and to report by letter to the Surgeon-General, S. O. 185, A. G. O., August 10, 1882. Granted leave of absence for four months. S. O. 188, C. S., A. G. O.

POWELL, J. L., 1st Lieut. and Asst. Surgeon. Confirms telegraphic instructions of this date to allow the Lieut.-Colonel Tenth Cavalry and Troops G and L of that regiment, and Asst. Surgeon Powell to continue, temporarily, and until further orders, at Fort Stockton, Tex. S. O. 84, Department of Texas, August 9, 1882.

MCCREERY, G., 1st Lieut. and Asst. Surgeon. Transferred from Fort Apache to Whipple Barracks, A. T. S. O. 119, C. S., Department of Arizona.

EBERT, R., 1st Lieut. and Asst. Surgeon. Relieved from duty at Fort Walla Walla, W. T., to accompany troop E, 1st Cavalry, to Boise Barracks, and on arrival there relieve Asst. Surgeon Wilcox from duty at that post. S. O. 106, C. S., Department of the Columbia.

RAYMOND, H. L, 1st Lieut. and Asst. Surgeon. Transferred from Whipple Barracks to Fort Apache, A. T. S. O. 119, Department of Arizona, August 3, 1882.

EGAN, P. R., 1st Lieut. and Asst. Surgeon. Relieved from duty at David's Island, N. Y., and to report in person to the Commanding-General Department of Arizona, for assignment to duty. S. O. 185, C. S., A. G. O.

WAKEMAN, WM. J., 1st Lieut. and Asst. Surgeon. Relieved from duty at Columbus Barracks, Ohio, and to report in person to the Commanding-General Department of the Platte, for assignment to duty. S. O. 185, C. S., A. G. O.

MACAULEY, C. N. B., 1st Lieut. and Asst. Surgeon. Appointed Assistant Surgeon, to date from August 10, 1882.

CHERBONNIER, A. V., Captain and Medical Storekeeper. Upon expiration of his present sick leave of absence to report in person to Lieut.-Colonel E. Swift, Assistant Medical Purveyor, New York City, for duty in the Medical Purveying Depot in that city. S. O. 188, A. G. O., August 14, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 19, 1882

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
August 12, 1882.	0	11	24	6	10	20	0	0
August 19, 1882.	0	33	28	5	9	29	0	0

DR. FRANCIS ATWOOD died at St. Paul, Minn., on the 5th instant, of typho-malarial fever, at the age of thirty-six. He had practised there eight years, and at the time of his death was unquestionably the leading oculist of the Northwest.

Dr. Atwood was a graduate of Harvard College, and of the Harvard Medical School, and studied his specialty with Williams and Von Graefe.

The following resolutions have been adopted by the Ramsey County Medical Society.

Whereas, In the Providence of God, our friend and associate, Francis Atwood, has been called away from us in the height of his usefulness;

Resolved, That as a society we hereby place on record our deep sense of the rare combination of qualities which endeared Dr. Atwood to us as a man and commanded our confidence in him as a physician.

Resolved, That, fully sensible of the loss that both our profession and the public have sustained in the death of Dr. Atwood, we deplore the event which has removed from us one so worthy in every way of the respect and esteem which he always inspired.

Resolved, That we tender to the wife and family of our friend our heartfelt sympathy in their great sorrow, and commend them for consolation to Him who is the only source of all true comfort.

Resolved, That a copy of these resolutions be sent to the family of Dr. Atwood, and that they be entered upon the minutes of this society, and be furnished for publication to the daily press of this city, to the Boston *Medical and Surgical Journal*, and to the New York MEDICAL RECORD.

D. W. HAND, *President.*

C. B. WITHERLE, *Secretary.*

HOMŒOPATHY IN THE GOVERNMENT SERVICE.—At the instigation of Philadelphia homœopaths and the

American Institute of Homœopathy, a joint resolution was introduced into the United States Senate by Mr. Don Cameron, and into the House of Representatives by Mr. O'Neil, of Philadelphia, which aimed to make it a misdemeanor for the army or navy medical boards to refuse to examine or, if qualified, admit homœopaths. The resolution was not adopted.

The National Board of Health is obliged to limit its work somewhat, owing to diminished appropriation. The Marine Hospital Service, however, has had $100,000 assigned it for use in helping local boards of health in case of epidemics.

The Chicago Medical Review no longer publishes a list of editors, but appears under the editorship of Dr. E. C. Dudley, with whom Dr. C. H. Lodor is associated.

Injuries from Toy Pistols, as well as deaths, have been very numerous in this city. On July 4th over fifty cases of children injured by these dangerous playthings were brought to our hospitals.

The Tenement-House Inspection now going on by the city Board of Health, continues to report good results from its work, particularly in the direction of educating the poor people to take care of their children and themselves. The mortality among children has, so far, not been excessive this season.

Surgeon-General Hamilton will lecture on surgery in the National Medical College, Washington, D. C., during the absence of Prof. J. Ford Thompson in Europe.

Sulphuric Ether is said to have the property of modifying the very persistent and unpleasant odor of oil of turpentine in mixtures.

Lycopodium can be put to an excellent use when sprinkled over oiled silk. It prevents the fabric from adhering together.

A Common Cause of Sick-Headache, according to Dr. Savage, of Jackson, Tenn. (*Med. and Surg. Reporter*, July 29, 1882), is hypermetropia and astigmatism, either alone or combined. The rational cure would therefore consist in wearing a properly fitted glass.

Natural History and "Education."—The following story is narrated by a correspondent in the *Students' Journal:* An English physician had recommended a patient to take plenty of horse exercise, so the gentleman went to a dealer's and looked at a horse, with the intention of purchasing it. He came back to the doctor with the following report: "I went," he said, "to the horse-dealer's, and saw a horse; he looked a very nice, steady animal, and I was going to buy him, but remembering it was a proper thing to look into a horse's mouth—but why I could not recollect—I put on my spectacles and examined his mouth. I was then delighted that I had not completed the purchase, for I found the poor suffering creature had lost nearly all his teeth; the only ones left that I could see being six on the top and six in the bottom jaw; and then came two great gaps without any teeth at all. I told the horse dealer it was cruel to keep a poor animal like that, without any teeth. The dealer assured me the animal had several more teeth in his jaws farther back, and I might put my hand in and try if I liked. I indignantly refused, however, to be taken in in this manner." Evidently in some "educated circles" the advance in natural history is quite astonishing.

Another Cure for Eczema.—Animal charcoal, freshly prepared and used as an ointment on the eruption, is a specific for eczema. So says Onocool Chunder Chatterjee, of India. That this remedy is a specific is unlikely, and that it is of marked value is improbable; but Dr. O. C. C.'s name is worth remembering.

Dr. Zoilo Perez, director of the *Journal El Criterio-Medico* has been elected a member of the Spanish Cortes.

The Princess d'Oettingen-Wallenstein has left fifty thousand marks to found a homœopathic hospital in Munich.

A Board of Health has been organized at Hot Springs, Ark., with Dr. L. S. Ordway as president.

Sanitarium at Elberon.—Mr. Charles G. Francklyn, in whose seashore cottage President Garfield died, has just founded and endowed a sanitarium for poor children, at Elberon, in memory of his young daughter, Gladys Francklyn, who died recently in Paris.

Invalid Loan Society.—In Newcastle, England, a new kind of organization has been established, called the Invalid Loan Society, whose object is the lending of clothing, furniture, and such other articles as will minister to the comfort of those who are both needy and sick.

Protection of the Natural Form of Woman.—In Kent, England, a band of young men, it is said, have established a society for the "Protection of the Natural Form of Woman," and, according to one of the rules of the society, bind themselves, "by demonstration, argument, and entreaty, to induce their sisters, and all ladies who are injuring their bodies for the sake of fashion, to sever the remaining link which connects the present generation with barbarism." By another of the laws the members promise to live a life of protest against the fashions so prejudicial to health.

Absorption of Sequestra.—M. Vrignal has lately made a series of experiments on the absorption of sequestra. He has determined that a sequestrum covered with pus will not be absorbed, while one enveloped in granulations will be. A fragment of bone (a bone peg) being driven into the tibia of a rabbit was almost entirely absorbed.—*Gaz. des Hôpitaux.*

A Modern Fable.—Some of the eccentricities of modern adulteration are delicately disclosed to the commonwealth of consumers by a contemporary German satirist, in the following neat little fable:

"There were once four flies, and, as it happened, they were hungry one morning. The first settled upon a sausage of singularly appetizing appearance, and made a hearty meal. But he speedily died of intestinal inflammation, for the sausage was adulterated with aniline. The second fly breakfasted upon flour, and forthwith succumbed to contraction of the stomach, owing to the inordinate quantity of alum with which the flour had been adulterated. The third fly was slaking his thirst with the contents of the milk-jug, when violent cramps suddenly convulsed his frame, and he soon gave up the ghost, a victim to chalk adulteration. Seeing this, the fourth fly, muttering to himself, 'The sooner it's over the sooner to sleep,' alighted upon a moistened sheet of paper exhibiting the counterfeit presentment of a death's-head, and the inscription, 'Fly Poison.' Applying the tip of his proboscis to this

device, the fourth fly drank to his heart's content, growing more vigorous and cheerful at every mouthful, although expectant of his end. But he did not die. On the contrary, he throve and waxed fat. You see, even the fly-poison was adulterated!"

THE WATER OF THE DEAD SEA.—Dieulafait found in one cubic centimetre of Dead Sea water enough lithia to show the spectrum of this substance at least a thousand times. The same water contains also so much boracic acid that it can be practically recognized in the residue from a single cubic centimetre of the water. Hence he infers that the present waters of the Dead Sea are the residues of the evaporation of an inland sea, analogous to the Caspian or the Kara Boghaz.

COMFORT AND DRESS.—The *Boston Journal of Chemistry*, August, 1882, has some apt and timely remarks on this topic, from which the following is quoted:

"One of the signs of advanced civilization is discomfort in dress: the farther any nation advances in civilization, the more she tortures her subjects, and, strangely enough, this infliction generally falls upon the so-called upper class. The educated class, the members of the liberal professions, the denizens of the city, the merchant and his clerks, suffer more than the poor laborer from heat, if not from cold. Advocates of 'dress reform,' who are trying to make women's dress more like men's, are asked to consider that the dress of a 'gentleman' is about as uncomfortable as if designed by the Evil One. It is the Western civilization of the nineteenth century that has developed this refinement of cruelty, compared with which pierced noses and lips and tattooed skin are most comfortable. The survival of the unfittest has led to its development, and now variations have ceased, so that there is no longer any chance for improvement or even change."

DUODENAL ULCER.—In the *Lancet*, Dr. Edward B. Gray reports a curious case of obscure chronic epigastric pain in a man otherwise apparently healthy, which teaches how difficult it is to diagnose duodenal ulcer. The patient, aged fifty-eight, had complained of pain "across the pit of the stomach and through the loins" for two years. He was well nourished, appetite good, epigastrium only slightly tender to pressure. He was regarded by his friends as a hypochondriac. Suddenly he vomited over twenty ounces of bright-red blood. He was ordered twenty minims of the tincture of the perchloride of iron every three hours, to keep to ice and iced water, and to remain absolutely at rest on his back. About midnight of the same day he passed between a pint and a half and two pints of clotted blood from the bowel. He passed no more blood, but two days subsequently he was suddenly seized with severe epigastric pain, fainted, and died in a few minutes. At the post-mortem, the stomach and intestines were found full of blood. The sole lesion discovered was a small, deep ulcer, of the diameter of a split pea, clean punched out of the otherwise healthy mucous membrane of the duodenum. At the bottom of the ulcer was a small perforation in the pancreatico-duodenal artery. The other abdominal organs were healthy.

MAN AND THE BACILLUS.—Dr. J. Milner Fothergill, in a letter to the *Philadelphia Medical Times*, referring to Koch's theory of the origin of tuberculosis, remarks, half jocosely: "Talk of the bitterness of death! It is nothing to the shadowy danger which overhangs us of a tubercle-bacillus getting into one's pulmonary alveoli in an unguarded moment, and when one's 'resistive power' happens to be impaired. Shadowy in the sense of invisible, not unreal! Is this what is meant by 'the doom of a great city?' Is the bacillus a relative of the poison-germ which slew Sennacherib's host in a night? We do not yet know the little creature intimately enough to say. But, really, the horrors which the mind conjures up of the dangers of the bacillus in the future are demoralizing. Suppose, now, that some change of the human constitution should favor the bacillus, just as the potato-field did the Colorado beetle, who had been happily quiet in his dietary of the leaves of the deadly nightshade, but who went on the war-path when the leaves of the other members of the Solanaceæ came within his reach. The imagination fails to conceive what may be the fate of man—to be slain by a foe more remorseless than any of the plagues of Egypt. Suppose, now, that the bacillus took such a new departure, and got ahead of our 'resistive power.' Why, man would be swept off the face of the earth! What an ignominious end, too! Man, in the plenitude of his power over the forces of nature, slain by an insignificant little bacillus!"

FALSE EYELASHES.—Labouchère says in *Truth*: "The Parisians have found out how to make false eyelashes. I do not speak of the vulgar and well-known trick of darkening the rim round the eye with all kinds of dirty compositions, or the more artistic plan of doing so to the inside of the lid. No, they actually draw a fine needle, threaded with dark hair, through the skin of the eyelid, forming long loops, and after the process is over—I am told it is a painless one—a splendid dark fringe veils the coquette's eyes."

HOW THE KAFFIRS TREAT MILK.—Milk hung up in a cow-skin sack till it becomes sour and thick is a staple article of food among the Kaffirs, and the milk-sack is such a sacred thing that no woman is allowed to touch it, and but one responsible man for the household has charge of it. A Kaffir who would drink sweet milk would be considered a babe.

ALCOHOL IN BURNS AND SCALDS.—Saturate a soft piece of fabric with alcohol, lay it over the burn, then cover it with cotton or finely picked oakum. This is the most cleanly dressing that can be adopted. It may be thought that alcohol applied to a burn will produce more pain; but try it, and you will be agreeably surprised to observe how quickly it will allay the pain; subsequently disturb the dressing as little as possible; wet the dressing occasionally with alcohol, and the result you will find better than by any other method.—*St. Louis Med. and Surg. Journal.*

THE RATE OF TRANSMISSION OF NERVE-FORCE.—René has made a large number of experiments upon the rate of transmission of nerve-force in man. He obtained $\frac{1}{50}$ of a second as the approximative duration of a cerebral act; and a rate of transmission of nerve-force in a sensory nerve of twenty-eight metres a second.

OXIDIZED WATER.—Paul Bert, following in the steps of M. Béchamp, has, by a series of experiments, discovered that oxidized water arrests fermentation from the presence of living organisms, but is inert in the presence of amorphous ferments (diastase, saliva, pancreatic juice, etc.).

Original Communications.

ON NERVE-STRETCHING.[1]

By W. J. CHANDLER, M.D.,
SOUTH ORANGE, N. J.

Part I.

The subject of nerve-stretching has recently attracted considerable attention in the medical world. It is not, however, a procedure of recent origin. Three hundred years ago, William Fabricius made forcible extension of the limbs for rheumatism and painful affections of the joints. But while this practice has never been lost sight of, its mode of action has been very imperfectly understood. Experiments in nerve-stretching were made by Harless and Haber in 1858; by Valentine in 1864; by Schleich in 1871; by Conrad in 1877; and more recently our knowledge of this subject has been very greatly increased by the labors of Neuman, Legaard, Vogt, Tarchanoff, Quinquand, Wiet, Brown-Séquard, and others (*Le Prog. Med.*).

Operative surgery may be said to have begun its labors in this direction when Billroth cut down upon the sciatic nerve expecting to find a neuroma. After a careful search, during which the nerve was lifted from its bed and more or less traction made upon it by the handling it received, no tumor was found. The wound was closed, somewhat to the chagrin of the operator. The patient, however, was relieved of his pain from the date of the operation. Here, then, was a successful case of nerve-stretching unwittingly done. Nearly three years later (February 15, 1872), Von Nussbaum, of Munich, performed the really first operation of nerve-stretching with a definite purpose. The case was one of spasmodic painful contraction of pectorals and flexors of the left arm and hand, caused by a bullet-wound in the neck and elbow. There was anæsthesia extending over the arm and the left side of the neck and face. During several years various modes of treatment (anodynes, stimulants, electricity, etc.), had been tried in vain. It was then that the illustrious surgeon determined to *cut down upon* and to stretch the nerves of the brachial plexus for the relief of the symptoms. The result was in every way satisfactory. The spasms were allayed, pain ceased, and sensation returned. It was about this time that Billroth appreciated the full significance of the results in his case, and published the details. These two operations opened a new field in surgery, into which surgeons looked with wonder, but were not apparently eager to enter. Paul Vogt, who published a small volume on this subject five years later (1877), was able to collect but fifteen cases.

Dr. J. H. Pooley (Columbus, O.), in August, 1880, published an article in The Medical Record (New York), with a summary of 67 cases, including those of Vogt's, and 30 cases of anæsthetic leprosy.

Fenger and Lee (*Journal Nervous and Mental Diseases*, New York, April, 1881) followed in April, 1881, with an admirably classified article and a brief account of 94 cases. One of the latest and most comprehensive articles on this subject, and one from which we shall frequently quote, appeared in the February and March numbers of the *Revue de Chirurgie*, Paris, 1882. These articles give a general review of the whole subject, and contain a tabulated list of 132 cases.

Professor Nocht, of Berlin, has collected 150 cases in which this operation has been performed, but I have been able to secure only a brief abstract of his paper (*St. Louis Clin. Rec.*, February, 1882).

The ground has been very thoroughly canvassed, and following these able writers, operators, and experimenters at so short an interval, I shall not be able to present much that is new; nevertheless, availing myself of their labors, and through the kindness of many friends in the profession, I am able to present to your consideration a much larger number of cases than has as yet been embraced in any single paper on this subject, and the conclusions drawn therefrom, by indicating the proper sphere and therapeutic value of the operation, may, I trust, be not unworthy of your attention.

ANATOMICAL LESIONS AND PHYSIOLOGICAL EXPERIMENTS.

In order that we may proceed intelligently, it is necessary to consider the changes that take place in the nerve and adjacent tissues when traction is made, *i.e.*, the *anatomical lesions;* and then to study the effects of these lesions in the dead and living animal —anatomical and physiological experiments. We gather most of these facts from Vogt, Quinquand, and Brown-Séquard, and are largely indebted to the excellent abstract made by Artaud and Gilson (*Rev. de Chirurgie*).

When the nerve of a living animal is stretched, there are certain changes wrought in the nerve-tubes, their sheath, and the capillary vessels. If the sciatic be examined one month after stretching, we (Latteux) find embryonic cells under the sheath, atrophy of the superficial fascicles, while the deeper fascicles are sound. According to Quinquand, the central fibres are intact; beside these are seen degenerated fibres, in which the myelin is clearly segmented. This degeneration commences at the point where traction was made, and extends along the tubes as far as the spinal ganglia, thus showing that stretching has a central action. It also, but not to so great a degree, extends along the peripheral extremity of the nerve. According to Shevving, this partial integrity explains the persistence of motility. Finally, beside these healthy and degenerated fibres, the microscope shows other fibres in the process of repair.

But these are not the only changes. The sheath and its vessels present equally important lesions. At the point of traction are numerous extravasations of blood. Above and below are also found extravasations in the sheath. These extravasations are always found in the same situation—the sciatic notch and the popliteal space, they are also found along the gluteal and peroneal vessels, *i.e.*, wherever the vessels for the nerves penetrate the sheath. These points have already been observed by Klum as being the favorite seat of disseminated neuritis.

These extravasations entirely disappear after five or six weeks. The fact that there are extravasations is shown (Vogt) by killing the animal with chloroform and injecting the abdominal aorta with the blue fluid of Thiersch. Portions of the sciatic nerve are then removed and hardened in alcohol and chromic acid. The microscope then shows dilatation of the vessels and numerous points of rupture. At these points the blue matter of the injection has entered the cellular tissue. This is al-

[1] Read before the New Jersey State Medical Society, May 24, 1882.

ways the case even when the operation has not given rise to any hemorrhage.

In some cases the sheath is sclerosed and thickened, and in all cases its adherence to the nerve is lessened.

Disturbances of nutrition take place *occasionally*, in the parts supplied by the nerve. The muscles may atrophy and the extremities (toes) slough off.

The important lesions then of nerve-stretching are, first, a loosening of the sheath of the nerve; second, extravasation of blood into the cellular tissue of the sheath; third, rupture of a portion of the nerve-fibres; fourth, dilatation of the vessels; fifth, nutritive changes.

ANATOMICAL EXPERIMENTS.

If we expose a nerve in the cadaver and to its free extremity attach a weight, we notice that while it has but little elasticity it is very *extensile*. By following Vogt we can show that this elongation not only takes place at the point where the nerve is exposed, but is distributed throughout its *whole length*. This distensibility diminishes from the centre to the periphery, and is proportioned to the normal movements of different parts of the body. By increasing the weights we shall finally reach the limit of distensibility and rupture the nerve. The point of rupture is variable, sometimes being near the attachment of the weight and again in a distant part of the nerve. Trombetta has ascertained the minimum weight, or force, necessary to rupture the different nerves in an adult man:

To rupture the sciatic				requires	84 kilos.
"	"	"	popliteal	"	52 "
"	"	"	crural	"	38 "
"	"	"	median	"	38 "
"	"	"	ulnar	"	27 "
"	"	"	radial	"	27 "

The force needed for therapeutic effects is not over one-half that required to rupture. A less amount of force is necessary in children than in adults, in women than in men, and in the feeble than in the robust.

PHYSIOLOGICAL EXPERIMENTS.

The results of Tutschek's experiments show:

First.—A single slight extension of the sciatic nerve increases reflex irritability in the corresponding limb.

Second.—A second extension immediately after the first diminishes that irritability.

Third.—A third reduces it below normal, but reflexes can still be produced.

Fourth.—A powerful stretching completely annuls all irritability.

The amount of force used likewise affects the *permanence* of the results. If the traction be slight, there result immediately anæsthesia, momentary spasms, and slight loss of motion. These effects all disappear within a few hours. If, however, the nerve is forcibly stretched, the paresis is greater, the anæsthesia more permanent, and the reflexes may temporarily disappear.

The *direction* in which traction is made is of importance. If the nerve be drawn in a direction *away from the spinal cord* there results anæsthesia with slight paresis. If the direction of traction be *toward the cord*, there results an equal amount of anæsthesia, but a greater paresis, together with a loss of reflexes. This is an important practical point, explaining why nerve-stretching is ineffectual in certain cases, and indicating a means for making it more effectual in others.

In neuritis (Vogt) stretching arrests the inflammation. This is shown by exciting a neuritis in a dog by an irritating injection into the nerve. Stretching is then done and the neuritis is checked. Some cases of optic neuritis (Wecker) seem to have been temporarily arrested in this way.

If the right sciatic of a guinea-pig be stretched there follows anæsthesia, not only of the parts supplied by the right sciatic, but also of those supplied by the left sciatic, and frequently of those supplied by the right and left crural; but while the anæsthesia in the right limb is persistent, that induced in the distant parts is transient. Again, if the right sciatic of a guinea-pig be stretched the usual anæsthesia of the right limb follows. Soon after the left sciatic of the same animal is stretched, and then follows not only anæsthesia of the left limb, but a *return of sensibility to the right limb.* This phenomenon (called by Quinquand "transfer of sensibility by irritation") proves that stretching has not only a peripheral, but also a central action.

One more experiment—that of Brown-Séquard, who makes in a guinea-pig a right lateral hemisection of the dorsal spinal cord. There immediately result a great hyperæsthesia and considerable loss of power in the right hind limb, while a very decided anæsthesia is produced in the corresponding limb of the other side. If now the left sciatic nerve be stretched, there follows in the left limb loss of power and a *return of sensibility*, while in the right limb the condition of hyperæsthesia is markedly increased. This hyperæsthesia is not confined to the region supplied by the sciatic, but extends to the region of the crurals, or even to the anterior extremities. It is always accompanied by a noticeable amount of motor paralysis. (Similar results were obtained by hemisections in the cervical regions.)

These experiments prove conclusively that stretching the sciatic nerve produces some *change* in the *nervous centre* with which it is connected, and *transmits* its effects through the *whole length of the spinal cord*, producing in the different parts of the body supplied therefrom certain more or less persistent *modifications* of *function*.

To sum up our knowledge from experiments, we conclude:

First.—That nerves are extensile, and can be elongated within certain limits without danger of rupture.

Second.—That stretching acts especially to interrupt the sensitive current, while it allows the motor current to pass.

Third.—That the motor current and reflexes are more affected by centripetal than by centrifugal traction.

Fourth.—That stretching acts on the nerve-centres, producing certain dynamic changes, and occasionally local disturbances more or less persistent.

Thus far scientific investigators have led us. Much that is of interest and practical benefit have they unfolded, but much is yet to be discovered, and we must leave this part of the subject still in the hands of those patient workers whose future researches will clearly establish many points at present obscure.

THERAPEUTIC VALUE OF THE OPERATION.

And now let us turn to the practical part of this subject and ask what benefit does nerve-stretching confer? Or, perhaps, at the present time, we ought to ask, "Does it confer any benefit whatever?"

We shall consider this (1) by a study of statistics as to *cure, failure, danger*, etc., and (2) by a review of the opinions of medical men.

To show what nerve-stretching has done, let me read briefly three cases:

I. (By Nussbaum.)—A Pole, aged thirty-five, eleven years previously fell from a height of six feet on a hard floor. He struck on his sacrum with sufficient force to produce complete paraplegia, with its attendant involuntary discharges. In time deep bed-sores developed and convulsions set in. At the time of the operation there were each day as many as one thousand clonic convulsions, during which the knees were violently drawn against the chest. The frequency and severity of the convulsions were rapidly exhausting the patient. It was then determined to stretch the crural and sciatic nerves of the right side. After the operation convulsions in the right leg ceased and sensibility returned. Two weeks later the left crural and sciatic were stretched with the same favorable results on the left side, and in addition voluntary power over the sphincters was regained. In ten days the patient, who had been eleven years in bed, was able to rise and walk about on crutches.

II. (George W. Callender, 1874.)—A man, aged forty-one, sustained a compound fracture of the wrist (1867). Twenty months later the arm was amputated at the wrist. Pain in the scar and painful twitching of muscles of the arm called for a secondary amputation, in 1869, at the elbow-joint. Pain still continued, and in February, 1871, a neuroma was removed from the stump, but without affording any relief. In July, 1872, the median nerve was divided, or excised (?), with no better effect. In January, 1874, the stump was painful, tense and glistening, and the pain extended along the corner of the median nerve, up over the neck and side of the face. Now at length, after seven years of suffering and four fruitless operations, the median nerve was bared down to the stump and thoroughly stretched. Immediately the pain ceased, the stump in a short time became normal, and the patient obtained permanent relief.

III.—But we are not compelled to travel three thousand miles to gather testimony. The operation has been done many times in this country, and several members of this Society, Dr. Dougherty, of Newark, Drs. William Pierson, Jr., and Buttner, of Orange, have contributed histories of interesting cases. One of these is a case of sciatica (Buttner) in a German, aged thirty-six years. The disease was of eight years' duration. Every known treatment at the hands of practitioners of different schools of medicine was unavailing, and the patient was steadily losing ground. The operation of nerve-stretching was decided upon and performed December 17, 1881. The right sciatic was exposed in its upper part and thoroughly stretched. The sheath was highly congested. The distention by stretching was sufficient to elongate the nerve about one and one-half inch. The wound was closed by sutures, and healing took place without suppuration. The pain immediately ceased, and except a little stiffness in the limb for two or three weeks after the operation, the recovery has been complete and permanent.

But all cases do not show such gratifying results. Failures are not infrequent, the relief is often only transient, and in some instances the symptoms have been aggravated by the stretching.

Let us then turn to the study of statistics. You will find in the tables appended to this paper a record of 400 cases.[1] Some of these 400 cases were not received in time to be incorporated in the tables, but will be found in the appendix with the unpublished cases. Of these, 270 were cured or greatly improved, 58 were temporarily benefited, and 60 failed to receive any benefit. In 10 cases the result is unknown, and 2 cases were made worse by the operation. Of these 60 failures, 34 were in traumatic tetanus, and 11 in locomotor ataxia and diseases of the nerve-centres. Removing these diseases, together with the optic nerve cases, we have remaining 260 cases, with only 14 failures, *i.e.*, less than 5½ per cent.; or, if we include among the failures the 6 doubtful cases, the total percentage of failures is but little more than 7½ per cent., leaving a balance of over 92 per cent. as temporarily or permanently benefited. This certainly speaks well for a rejected (?) operation, especially when we consider that in most of these cases relief had been sought in vain from every other source.

We shall gain a clearer idea of the proper field for the operation by considering separately the results in different diseases. There have been treated by nerve-stretching the different forms of neuralgia, spasmodic affections, contractures, epilepsy, paralysis, diseases of the optic nerve, anæsthetic leprosy, tetanus, and various diseases of the spinal cord.

(*a.*)—NEURALGIAS.

We have collected of sciatica, 70 cases; of neuralgia fifth pair, 37 cases; of traumatic neuralgia, 15 cases; of all other kinds of neuralgia, 30 cases.

1. *Sciatica.*—We have 70 operations for the relief of this affection. In 1 case only did it completely fail. In 3 cases it gave but a transient relief, and in 1 case the result is not recorded. In all the others (68 cases, 97 per cent.), the patients were either cured or greatly improved. In most of these cases the disease had existed for months or years. Some of the patients were bed-ridden, all were more or less crippled and discouraged. With a present full of torment, and a future holding out no hope of relief, some were sinking into a despondency which would either render them an easy prey to disease, or lead them to a more pitiable end—self-destruction. If from such a hopeless, helpless wreck, we can restore over ninety-seven per cent. to health and usefulness, we will do well to value the means by which such a transformation is effected.

Just here there is a very pertinent objection as to the permanency of the results. Many cases are reported soon after the operation as cured, when a longer observation shows a return of the disease. No one more than myself feels the force of this objection. I have carefully examined the reported cases, and have communicated with many of the operators in order to verify and correct the results, and I am satisfied that the record is essentially correct. But grant that some of these cases may relapse, permanent relief is still the *rule*, and those temporarily benefited are satisfied to have had even a transient relief from pain. As one patient expressed himself, "I would be willing to have my sciatic stretched every month if it would give me as much relief as I have had for the six months following the operation."

In several of the cases the effects of a first stretching were transient, while a second stretching was

[1] These tables will be given in Part II. of this article, in the next number of THE RECORD.

followed by complete recovery. In some cases a *slight amount* of traction has been followed by a transient effect, and necessitated a second more vigorous stretching to complete the cure. Or again, the force used has been too great, and has produced an unnecessary motor paralysis.

In chronic cases presenting considerable muscular atrophy the benefit is less complete. The atrophy is sometimes never entirely overcome. In those cases of central origin (cancer of envelopes of cord, etc.) less encouragement is afforded as to complete recovery. But in idiopathic cases of sciatica, those, too, which have resisted all other modes of treatment, we must consider nerve stretching as one of the most effective remedial agents we possess.

2. *Neuralgia of the fifth pair of cranial nerves.*—We have collected 37 cases, 29 of these are reported cured and 12 temporarily relieved. There were four failures, and in one instance the result is not recorded. In some instances of failure or temporary relief a subsequent excision of the nerve has been followed by recovery; although in one case (Lange) the division of the nerve in Europe, and a subsequent division some years later in this country, was followed by relief for only three months in each instance, yet an elongation done four months ago has, up to the present time, given perfect relief. In general, the result is not nearly so favorable after stretching the different branches of the fifth pair as after stretching the sciatic for sciatica. In other words, we must not expect to cure by nerve-stretching more than one-half of the cases of facial neuralgia met with. Over eighty per cent. will be either improved or cured, and about one case in every six will fail to receive any benefit whatever.

3. *Traumatic neuralgia.*—The results are very much the same as in the neuralgias not traumatic. Indeed, we do not see that the traumatism has any especial bearing upon the result. At the same time they are generally classified separately, and we have included 15 cases under this head. Of these 7 were cured, 4 permanently improved, 2 temporarily improved, 1 failed and in one case the result is not recorded. We can say that 11 cases (63⅔ per cent.) were cured or greatly benefited, while not over 2 cases (13 per cent.) failed.

4. There remain of the different forms of neuralgia 30 cases. Nineteen were cured, 3 greatly benefited, 2 temporarily benefited, 3 failed, and 3 are doubtful. Eight of these cases were accompanied by painful spasms, which, in some of the cases, were entirely and permanently allayed by stretching. In Nussbaum's celebrated case of intercostal neuralgia there was a temporary relief (Fenger and Lee), but the patient had become addicted to the opium habit, and his otherwise enjoyable respite was marred by the cravings of an insatiate appetite. The pains, however, soon returned, and as far as nerve-stretching is concerned the case is a failure.

The percentage of cured and improved in the different neuralgias are as follows: Sciatica, 97 per cent.; neuralgia of the fifth pair, 80 per cent.; traumatic neuralgia, 66 per cent., and various other forms of neuralgia, 75 to 80 per cent.

Considering the neuralgias as a class, we may safely conclude that they are appropriately and efficiently treated by nerve-stretching. We would not, however, advise a precipitate rushing into nerve-stretching as the initial step in the treatment of neuralgia, nor shall we be disappointed if the accumulation of statistics, and the results of longer observations shall somewhat lessen the percentage of cures; but we are well satisfied that many, *very many*, of the obstinate, intractable cases of neuralgia will be by the aid of nerve-stretching no longer an *opprobrium medicorum*.

(*b.*)—SPASMODIC AFFECTIONS.

Next to the neuralgias, the spasmodic affections offer a favorable field for nerve-stretching.

1. *Mimic spasms; spasms of the seventh pair of cranial nerves, or tic non douloureux de la face.*—There are 14 cases reported; 12 cures, 2 relieved (Hahn). The duration of the disease was from one to ten years. The facial nerve was stretched in all cases except one (Davidson's—infra orbital). The situation at which it was exposed was just at its emergence from the stylo-mastoid foramen. In one case it was exposed anterior to the ear (under the zygoma). The spasms ceased in all cases immediately after the operation. Facial paralysis followed in *every case;* and while it was ultimately recovered from, its duration was never less than two weeks, and, in one instance, it continued for five months.

It is well, then (as suggested by Artaud and Gilson) to weigh this fact in considering the advisability of the operation in individual cases, and to warn patients of the temporary inconvenience they must expect. We conclude, then, that nerve-stretching is a very proper procedure in these cases, inasmuch as it has never entirely failed, and, in nearly ninety per cent. of the cases has wrought a complete cure.

2. *Torticollis, or spasmodic affections in which the spinal accessory has been stretched.*—There are 11 cases; 7 cured, 3 relieved, and 1 unrelieved. In all cases the disease had existed for many years; in one case (Southam), twenty-three years. In one (Studsgaard), the movements of the head were rotary; in four, nerve stretching alone was performed; in six, exsection was combined with stretching. The results seem rather to favor the combined operation, although we think the operators were perhaps a little hasty in following with excision so soon after stretching, especially as two of the cases, in which stretching alone was done, were cured. In all these cases except one, the spinal accessory was the nerve stretched. Southam gives an account of the method of exposure and stretching of the nerve (*Lancet*, November, 1881).

We have included one case by Blum, in which a tremor of the leg was cured by stretching the sciatic. The patient was a girl of eighteen years, who had been hysterical from childhood. For four months the right leg had been in a constant state of tremor, and, while walking, became œdematous and congested. Rest in bed relieved the œdema, but the tremor persisted. The right side was anæsthetic, while hyperæsthesia existed on the left side. The sciatic was painful on pressure. The tremor ceased immediately after the stretching, sensation returned, and motility was unimpaired.

(*c.*)—CONTRACTURES.

There are 5 cases in the table; 2 cured, 2 failed, and 1 died during the operation, from the entrance of air into the veins. There are a number of cases of other diseases accompanied by contracture of the limbs, in which nerve-stretching has been done; but the results do not seem to be very encouraging, so far as the correction of the contracture is concerned. Nussbaum's case (No. 5) stands as a bright exception. We have not cases enough to pass judgment

as to the propriety of the operation, further than to say that it is admissible and might be undertaken when other means have failed and circumstances do not contra-indicate it.

(*d.*)—PERIPHERAL PARALYSIS.

Thirty-nine cases are found in the tables; thirty-three of these were due to anæsthetic leprosy, all of which were more or less improved. Reports of these very interesting cases are found in the *Indian Medical Gazette* and in the London *Lancet*. The permanency of the improvement it is not yet possible to safely affirm, as Bomford (*Lancet*) says in only a few instances has he been able to observe the patients for any length of time afterward. In one case which he reports the improvement persisted after a lapse of four months, so that the patient was able to do hard manual labor. Wallace reports a case (Fenger and Lee) in which recovery of sensation was perfect, the discolored skin became normal, and pain entirely disappeared. At the end of two months these conditions still prevailed, and the prospect of permanent recovery was encouraging.

There are 3 cases of infantile paralysis, 2 of which were not improved; 1 (Simon) was greatly improved. The boy, five years of age, had for three years suffered from a partial paralysis of the right leg. Treatment had been of little service; electricity had been used for two years without much benefit. Stretching the right sciatic was followed by rapid muscular development and a great improvement in the mode of walking. Dr. S. thinks the procedure is harmless, and, in many cases, may render aid otherwise unobtainable.

The three remaining cases of paralysis were paralysis of the hand and arm. The ulnar, median, and radical were the nerves stretched. Two were much improved and one was entirely cured. These results are unexpected and decidedly encouraging.

(*e.*)—EPILEPSY.

We have 4 cases—1 (Nussbaum's) reported cured, 1 greatly improved (Gillett's), and 2 (Czerny and Morton) only slightly improved. In all these cases there was an aura from the region of the nerve stretched. Prof. Nocht considers these results as hopeful; and perhaps they are relatively so when we consider the intractable nature of the disease we are seeking to cure. But, as with the contractures, we must wait until a much larger number of cases can be collected, before we can decide upon the value of the operation in this affection.

(*f.*)—DISEASES OF THE OPTIC NERVE.

It is surprising that any one should have thought of applying the operation to this nerve, and still more surprising that he should have been bold enough to put the idea in practice. It does not seem that one would be justified in stretching the optic nerve, even in cases which have been considered hopeless. Nevertheless, Kummel has stretched the optic nerve seven times without any bad effect. All the patients were blind. Once he observed œdema of the retina, but no hemorrhage nor any inflammation of the nerve. In some cases of atrophy there was slight benefit.

Wecker, of Madrid, reports similar investigations and negative results. We have not the details of any of these cases.

(*g.*)—DISEASES OF THE NERVE-CENTRES.

The value of nerve-stretching in these diseases has been very generally discussed of late, and the tenor of these discussions has done much to bring the operation into disfavor—far more than its merits in other affections should have allowed. Indeed, it was its success in these other diseases which caused its trial in the as yet incurable diseases of the spinal cord, and because an equal success has not resulted, the real value of the operation has been overlooked. We have collected 81 cases. In 14 the operation may be said to have failed; in 1 the result is not recorded; all the others (66) were benefited.

There are 57 cases of nerve-stretching for locomotor ataxia. In 16 of these the improvement was so decided and persistent that some of them have been reported in other papers as cured. We prefer to record them as "*improved*," as there are good reasons to believe that in this disease all cases operated on will, after a time, relapse. Twenty-seven received only temporary (few days to a few weeks) benefit. In 13 cases there was no improvement. In 1 case the operation seemed to be the cause of increased suffering.

These results show that 33 per cent. may be greatly benefited, that 40 per cent. may be temporarily relieved, while in 25 per cent. we must expect to see the operation fail entirely.

Dr. H. J. Boldt (New York), who furnishes six cases for this paper, concludes that in ataxia the "stretching of nerves is only to be advised for the relief of symptoms," and even then the "result is variable." He thinks it better to stretch the anterior crural than the sciatic in these cases.

Prof. Langenbeck (Berlin) attaches considerable importance to the method of operating. Stretching the sciatic in its middle or lower third is followed by less atrophy of the limb, as the muscular branches are mainly given off above this point. He considers that cicatricial tissue, by irritating the nerve, may give rise to troublesome symptoms. He conducts his dissection with the utmost care, and avoids, if possible, the division of a single muscular fibre.

As to the propriety of the operation in locomotor ataxia, he considers that while relapses have very frequently occurred, the relief afforded fully justifies the operation; and I trust that there are none who have witnessed the extreme suffering produced by this disease, who are not prepared to accept the correctness of this conclusion.

(*h.*)—TRAUMATIC TETANUS.

Fifty cases of traumatic tetanus, treated by nerve-stretching, were followed by recovery in 10 instances. There were 37 deaths, and in 3 cases no result is reported. These figures do not encourage very sanguine expectations as to the success in nerve-stretching in tetanus; but then we must remember that no other mode of treatment for this disease shows very flattering results. In many of the cases that terminated in death, the operation procured very complete relief from pain and spasm; in other cases, no such relief was obtained. It has been objected that the operation was an additional source of irritation; but we are convinced that if done early, and under an anæsthetic, it can do no possible harm. On the other hand, there are strong grounds for the belief that when the lesion can be localized, and the affected nerve discovered, the operation may, in a certain proportion of cases, do immense good. Again, it is objected that the recoveries were due to other means (medicines) than the operation. While the physician will not generally dare to risk his patient's life by omitting to use any available therapeutic agent, this has been

done in two instances, and the result left entirely to nerve-stretching. One of these cases recovered. We conclude, then, that it is a safe adjuvant to other treatment; and while it does not offer strong hopes of success, we cannot refuse its possible benefits to the subjects of this much-dreaded disease.

Prof. Nocht reports 24 cases; 4 cured by operation alone; 2 by operation and medication; in 3 no change at all; balance, temporary relief (*St. Louis Clin. Rec.*, February, 1882). Fenger and Lee reported 21 cases, with 9 recoveries (*Am. Jour. Nervous and Mental Diseases*, April, 1881). Artaud and Gilson report 28 cases, with 7 recoveries (*Rev. de Chir.*, March, 1882). In the tables accompanying this paper there are 50 cases, with only 10 recoveries. It is a somewhat significant fact that the larger the number of cases, the smaller the *percentage* of cures. We are inclined to think, on the theory of probabilities, that the percentage of recoveries will not be any less than that recorded in this paper (20 per cent.), and may perhaps exceed that recorded by Nocht or Artaud and Gilson (25 per cent.).

DANGERS.

The *dangers* of the operation are in general the dangers of any surgical operation. Five deaths have been reported. One, however, was due to chloroform (Langenbeck). A second was due to the entrance of air into the veins (Gartner). These are not justly chargeable to the operation. I cannot judge of the other cases, as the details are too meagre. Practically, there seems to be little to fear as far as life is concerned. There are other dangers, such as erysipelas, ulceration, hemorrhage, sloughing, keratitis, paralysis (not persistent), and occasionally syncope and convulsions, which it is well to remember, although they are infrequent and generally of trifling importance. It is not impossible, however, that violent and repeated stretching (Table (*g*) case 73) may produce shock enough to the central nervous system, already the seat of extensive organic changes, to precipitate the fatal termination, and it is proper to avoid very forcible traction in diseases of the nerve-centres.

The study of statistics leads us then to a most hearty endorsement of the operation in neuralgic and spasmodic affections, and to at least justify its use in tetanus and in some diseases of the spinal cord.

(To be continued.)

LAUDANUM TO INFANTS.—A fatal case of poisoning of an infant is reported from Keyworth, England, and is remarkable for the alleged smallness of the dose. A "drop" of laudanum was administered one afternoon with castor-oil, to an infant, three weeks old, for the cure of diarrhœa, to which the child had been subject from its birth. Shortly after, the child became suddenly very ill. At half-past five on the same afternoon it was seen by a physician, when the child was lying with contracted pupils, livid lips, skin covered with perspiration, small pulse, and slow respiration. It could be roused with difficulty, and speedily relapsed into its former state. Notwithstanding the administration of emetics, and the use of cold affusions, the child died thirteen hours after it was first seen. Death from one drop of laudanum has occurred before, but the repetition of an ascertained case of death after such a dose is worthy of record, if only to impress on the public and the profession the danger attending the administration of opium in any form to young children.

A CONTRIBUTION TO THE SURGERY OF THE LIVER.

BY JOSEPH RAUSOHOFF, M.D., F.R.C.S., ENG.,

PROF. OF ANAT. AND CLIN. SURGERY, MED. COLL. OF OHIO.

CHOLELITHECTOMY.

OPERATIONS on the biliary passages are not recent additions to surgical procedures. Although practised by Petit and others, and compared with similar operations on the urinary bladder, cholecystotomy could not maintain rank in the list of recognized operations. Lost for more than a century, its reinstatement was counselled by Thudichum, who, in 1859, expressed, in the clearest language, his approval of this operation, and even indicated the steps to be taken in performing it. Although Hanfield Jones and Murchison likewise indorsed operations on the biliary channels, it remained for our distinguished countryman, Marion Sims, to attract to them, in his practical way, that attention which is demanded by the importance of the diseases that attack the parts involved. Since the first unsuccessful operation, the gall-bladder has been incised by Kocher, Lawson Tait, and Keen. I would not include the cases of Brown and of Bryant, since in that of the former it was merely a felicitous accident that the gall-bladder emptied its contents externally, and in that of Mr. Bryant the operation consisted in nothing more than the splitting of an old-standing fistula.

A close scrutiny of the recorded cases of cholecystotomy reveals the fact that in none was the diagnosis accurately made, and in those in which an operation led to the removal of calculi, their detection was neither more nor less than a fortuitous incident. Precision of diagnosis has not even been deemed a pre-requisite of grave operative interference. In the case of Dr. Sims it was undecided whether the tumor was a cyst connected with the liver or a dropsical gall-bladder. In Mr. Tait's case the diagnosis lay between distention of the gall-bladder, tumor of the head of the pancreas, and enlargement of a floating kidney. In the cases of Kocher and Keen alone was a positive diagnosis of dropsical distention of the gall-bladder determined upon prior to the operation. Mr. Tait, in the remarks upon his successful case, observes that "fortunately our advanced practice in abdominal surgery makes our limited power of diagnosis in such cases of less importance," and he thoroughly agrees with Sims in that "we should not wait till the approach of fatal symptoms puts the diagnosis in unmistakable fashion, but that we shall make an early exploratory incision, ascertain the true nature of the disease, and then carry out the surgical treatment that the necessities of the case may demand." Nevertheless, the nature of the operative procedures to be adopted depends upon the character of the lesion and its accurate recognition. Who would open the abdomen for simple distention of the gall-bladder when aspiration not only gives temporary relief, but, when repeated, as in the case of Kretzschman, may lead to complete recovery? Unless a gall-stone, *obstructive* in its position, is positively recognized, one may be pardoned for doubting the justifiability of an exploratory incision until the safer method by repeated aspiration has been faithfully tried and found useless.

Thanks to the comparatively fixed position of the gall-bladder and large biliary passages, the diagnosis of an impacted gall-stone should not and does

not offer insurmountable obstacles. The following case will illustrate this fact, and the operation based upon it, so far as known to me, is the first projected with a distinct object in view; namely, the removal of an impacted calculus. For the history of the case, up to the time of operation, I am indebted to Dr. James T. Whittaker, the attending physician, who has kindly furnished me the following:

H. B——, aged seventy-six, has been deeply jaundiced for six months. During this time he has lost fifty pounds in weight. His stools are like putty; his urine has the color of tar. His general strength is so much reduced that he is not able to sit up longer than half an hour. He is tortured with tinnitus aurium. He has no appetite, and is profoundly dejected.

The liver is enlarged; its free border projects two and one-half inches below the margin of the ribs. The gall-bladder constitutes a large tumor, of the size of the fist, smooth, globular, and movable. There is some apparently slight ascites. It was apparent that the condition depended upon total occlusion of the common duct.

The diagnosis rested between gall-stone and cancer. In favor of cancer was the enlargement of the liver and the ascites. In favor of gall-stone was the condition of the gall-bladder. Against both conditions was the total absence of pain. He was a very intelligent man, and he stoutly maintained that he had never had an attack of pain. His daughter stated that he had suffered from pain five years ago, a fact which he could not recollect, but had never had pain since. Against cancer was the absence of any primary deposit.

In order to definitely determine the diagnosis, I concluded to explore the gall-bladder. Having fixed it by compression from below upward against the liver, I introduced the needle of the hypodermic syringe and withdrew it full of thin, clear bile. On the next day, April 20th, I fixed the gall-bladder, as before, and gradually and slowly pushed through the abdominal parietes, just below the gall-bladder, a long, fine needle, in fact, the longest and finest needle of the Dieulafoy aspirator set. After penetration of the peritoneum, there was no resistance whatever—it was as if in empty space—to the farther progress of the needle, which I advanced slowly and in a straight line in the direction, as nearly as could be determined, of the common choledochus duct. At the depth of four and three-fourths inches I struck a stone. The sensation was perfectly clear and distinct. It was a fine, delicate crepitus, unmistakable in its character. After penetration of the skin, there was no sensation whatever on the part of the patient. The needle was then withdrawn, and the patient experienced no more discomfort than after a hypodermic injection. Having had all the dangers of cholelithectomy freely set before him, in the presence of his family, and fully recognizing that he was slowly dying by inanition, feeling "life not worth living," as he said, he elected to take the risks of the operation.

On April 29th Dr. Whittaker and I had no great difficulty in detecting a calculus by the method described by him. An operation was now definitely determined upon at the request of the patient. It was performed on May 3d, in the presence and with the assistance of Drs. Whittaker, Dunham, Cilley, Kebler, French, and Davis.

Operation.—The patient having been etherized, the position of the gall-bladder was accurately fixed and an incision four inches in length made over it. It was made parallel to the median line, and extended a little below the umbilicus. To check hemorrhage, hæmostatic forceps were used and left in place until the peritoneum was reached. When all bleeding had been stopped, this was incised on the finger. A knuckle of intestine and fold of omentum now protruded from the wound, but were easily repressed by an assistant. The gall-bladder, distended to the shape and size of a large pear, then presented itself in the wound, from which there escaped about a quart of ascitic fluid tinged with bile. The hooded needle of an aspirator was next plunged into the most prominent part of the gall-bladder, and eight ounces of a light-green fluid withdrawn. The last two ounces were of grumous character and appeared to be the thickened secretion of the gall-bladder. With the finger in the abdomen, the latter could easily be traced to its termination in the cystic duct, where a firm concretion was readily detected. Having thus confirmed the diagnosis, the gall-bladder was fixed by three wire sutures to the upper portion of the wound and incised over a distance of one inch. The finger, introduced through this aperture, immediately came in contact with one large and two small calculi, which were easily withdrawn. The obstructing calculus, wedged in the cystic duct, could only be dislodged by extraneous pressure with the finger in the abdominal cavity. This accomplished, its seizure and extraction was easily effected. A fifth stone was next removed, but proved to be a fragment chipped from the impacting calculus. The gall-bladder was now empty and a probe introduced into the duct met with no obstacle. The omentum and loop of intestine were now thoroughly cleansed with carbolized water, the lower portion of the gall-bladder fastened by four sutures to the margin of the abdominal wound and the latter closed. A drainage-tube having been placed into the opening of the gall-bladder, iodoform was dusted upon the surface of the wound, the latter covered with a thick layer of absorbent cotton and a bandage applied. A hypodermic injection of one-half grain of morphia was then administered and the patient placed in bed. Time of operation, one hour.

Notwithstanding his age, the patient recovered admirably from the operation. One hour after it he was perfectly conscious and free from pain; pulse 84, and of good tone. Eight hours later his condition had not changed. He seemed cheerful, and desired to see the stones. About twelve hours after the operation, the cotton was found so saturated with a greenish discharge that the dressing was changed. From this time on the patient gradually sank. The pulse became more frequent, feeble, and irregular. The condition of stupor, which had supervened, became more and more pronounced until the patient succumbed, twenty-six hours after the operation. A post-mortem examination was not granted.

The large stones removed weighed one hundred and thirty-eight and one hundred and sixty-two grains, respectively. The unimpacted one was composite in character and of the shape and size of a pecan. The obstructing calculus was distinctly conical in shape, of dark-green color, and quite friable. It was evidently of quite recent formation. The smaller stones weighed nine, five, and four grains, respectively.

The immediate cause of death was failure of the heart's action, which stimulants, faithfully given, were unable to avert. That death would probably result

from the operation was expected by the patient and his family as well as by myself. The fact that it was the only means of saving a life that would have ended at best in a month, must stand as justification for so perilous an undertaking in one so old. The possible existence of a stricture of the cystic duct, although considered before the operation, did not warrant the denial to the patient of his only chance for life.

HEPATOTOMY.

Mrs. G——, aged thirty-two, mother of one child. The family history is good and patient always enjoyed good health until the beginning of her present illness. About five months after her confinement, she observed an increasing loss of strength and flesh, which continued until she became bedridden and was treated for what was supposed to be typhoid fever.

At the time of her admission to the Good Samaritan Hospital, January 7, 1882, the patient presented a greatly emaciated appearance and features pinched and distorted from long suffering. Her appetite was poor and particles of partially digested food were passed with the diarrhœal discharges, which numbered three or four daily. The patient complained of constant pain in the abdomen, and was harassed by dyspnœa which compelled her to retain a semi-recumbent posture. There was a slight cough which yielded a light, frothy expectoration. The hectic condition into which the patient had fallen, accounted for the profuse night-sweats which were of nightly recurrence, and attended by an elevation of temperature of from three to five degrees.

Physical examination.—Thorax greatly emaciated. Percussion and auscultation revealed no serious lesions of the thoracic viscera. Moist râles heard over both lungs. Heart normal, urine scanty, but normal.

The epigastric region was bulged out by a smooth, round swelling, which could be traced along the inferior margin of the chest-wall to within two inches of the axillary line. The tumor was very sensitive to the touch, yielded a flat sound on percussion and a distinct fluctuation. The attending physician, Dr. James T. Whittaker, made the diagnosis of an hepatic abscess and verified it by removing a small quantity of matter with a hypodermic syringe. Nearly two weeks of entreaty were required to obtain the consent of the patient to permit the evacuation of the purulent accumulation.

January 19th.—Three pints of thick, creamy pus were removed by means of an aspirator, a medium-sized needle having been thrust into the most prominent part of the swelling. The pus removed contained the elements of bile, but presented no detritus of liver-cells. For a few days after the operation, a marked amelioration of all the symptoms was witnessed. The pain and dyspnœa subsided, the appetite improved, and the night-sweats were less exhausting. One week after the aspiration it became evident that the sac was refilling, and in two weeks the tumor had regained its greatest dimensions. About this time (February 3d), there was observed a sudden clearing up of all the symptoms. The size of the swelling decreased and the patient felt in every way improved. An examination of the diarrhœal evacuations revealed the presence of a considerable quantity of pus, and for a week this discharge continued. With the disappearance of the pus from the stools, the swelling again increased in size and the general condition of the patient grew worse.

February 22d.—Two pints of pus were evacuated by aspiration, and one pint of tepid water, containing one ounce each of tinct. iodini and kali iodid., injected into the abscess cavity, where it was kept for fifteen minutes, when as much of it as possible was withdrawn. Although it was evident that the sac was not completely emptied, nothing more could be drawn into the aspirator. This tapping did but little good, for in ten days the patient had relapsed into her previous condition of dyspnœa, hectic, and exhausting night-sweats. In addition to these symptoms there now supervened most violent vomiting and gradually increasing œdema of the lower extremities. Seeing the uselessness of aspiration, owing probably to the presence of loose shreds of hepatic tissue, I concluded that in a free incision lay the only chance of the patient's recovery. Her condition at this time was almost moribund in character. Evening temperature, 103° to 105°; pulse, 120 to 150.

Operation.—March 9th, in the presence of Drs. Whittaker, Conner, Seely, Reamy, Kebler, and members of the class, the patient was placed under ether after two ounces of brandy had been given. By inspection and deep palpation it became evident that the abscess was irregular in shape, presenting the appearance of two quite distinct tumors, which were connected with each other and extended below the umbilicus. Over the most prominent part of the larger tumor an incision was made with the thermo-cautery. This incision, five inches long and extending to within an inch of the umbilicus, was made parallel to and two inches to the right of the median line. The peritoneum was next divided upon a grooved director and the abdominal cavity opened. Interposed between the abdominal wall and the surface of the liver there appeared a fold of the great omentum which, although not bound to the liver, could not be drawn aside. This having likewise been divided with the platinum knife, the surface of the liver was exposed and found normal in color and without a trace of adhesive inflammation. The liver was now attached to the wound in the abdominal wall, by means of six silver-wire sutures, two of which were placed on each side and one each to the upper and lower extremities of the incision. The wires were introduced by means of a canulated perineal needle and included the entire thickness of the abdominal wall, omentum, and one inch of the sac wall. Thus, when all the sutures were in position, an area of hepatic surface about one inch wide and three inches long was exposed. Along the entire length of this surface, I now made an incision with the thermo-cautery, the thickness of the liver-tissue divided being one-half inch. Vent was thus given to three and one-half quarts of pus. It flowed as from a spring, and at times was streaked with quantities of retained bile.

By this time the patient was all but pulseless, breathing badly, and apparently in articulo mortis. Injections of whiskey revived her sufficiently to permit the completion of the operation, which consisted in washing out the abscess cavity with a five per cent. solution of carbolic acid, and in the insertion of two drainage-tubes one-half inch in diameter and ten inches in length. Iodoform having been dusted upon the wound, this was covered with a thick layer of absorbent cotton and a bandage applied. Fearing the effects of immediate removal to bed, the patient was kept on the operating table for several hours, during which stimulants were administered and heat applied to the surface. Ten hours after the opera-

tion the patient had rallied sufficiently to converse in a feeble voice. She was entirely free from pain and relished the half ounce of brandy given every hour. Pulse, at this time, 120, and very feeble. To insure rest, a fourth of a grain of morphia was given hypodermically.

March 10th.—The patient passed a comfortable night, although at midnight a cold perspiration had supervened.

In the morning the bandage, which had been thoroughly saturated with pus, was removed, together with the drainage-tubes, and the cavity washed out with water at a temperature of 120° F. Beginning at 9 A.M., a constant stream of water, entering through one tube and discharging through another, was permitted to run through the abscess cavity until 5 P.M., with one hour's intermission. This continuous irrigation not only insured a thorough cleansing of the cavity, but felt very grateful to the patient, who slept several hours during the process. In the evening the wound was dressed as after the operation. Alcoholic stimulants, and a hypodermic injection were administered as on the previous day. Beef-tea and milk were frequently given.

During two weeks the process of irrigation, by means of a double syphon, was continued with good results. After the wound was thoroughly cleansed, a laryngoscopic mirror was introduced into the abscess cavity, and the enormous surface carefully surveyed by reflected light. This method of examination proved very useful, as it enabled me at different times to remove three large sloughs, each of which would have covered the palm of the hand. Even continuous irrigation did not suffice to effect their removal, as they had gravitated to the floor of the cavity and were too heavy to be washed out by the current of water. By the reflected light the pulsations of the aorta could be seen as they were imparted to the posterior wall of the abscess. At each dressing iodoform was dusted on the wound and into the drainage-tubes.

From the time of operation the vomiting and dyspnœa ceased. The swelling of the lower extremities disappeared within three days, the cough became less frequent, and the appetite increased so that it soon became ravenous. This led to the suspicion that sufficient liver-substance to sustain life had not been left—a suspicion soon dissipated by the improved appearance of the patient. The diarrhœa and night-sweats yielded to the exhibition of aromatic sulphuric acid and tonic doses of quinia. The discharge gradually diminished as the cavity became smaller, and the drainage-tubes were shortened. Six weeks after the operation the sutures were removed, and on measurement the cavity was found to hold about one ounce of fluid and discharge about two drachms of pus in a day. The wound granulated rapidly from sides and floor, and two months after the operation nothing but a sinus, one inch in depth, remained. This has completely closed, and nothing but a large stellate cicatrix remains to show that an operation has been performed.

Remarks.—The successful case which I have taken the liberty to report, presents a number of noteworthy factors. It illustrates, in the first place, the good results that can at times be obtained by appropriate interference in even the most desperate cases, and when death seems all but present. Again, it is a fair example of a large proportion of cases in which aspiration can be of no avail so far as the cure of the disease is concerned. Regarding this method of treatment, evidence derogatory to its efficacy is fast accumulating. Two years ago there died in one of our hospitals a man from whom, at four different times, I removed no less than three hundred ounces of pus. An operation of the character practised in the foregoing case, had it been permitted, would probably have resulted in recovery.

When repeated aspirations fail to bring about relief, what surgical measure is to be practised? In England, and particularly in India, whence so much of our knowledge of hepatic affections is derived, puncture by means of a large trocar is a favorite method. Murchison had already adopted a similar practice, allowing the canula to remain in position for two or three days in the hope of establishing an adhesive inflammation. Most of the cases thus treated succumbed to peritonitis. In a recent volume of the *Lancet*, Funnel reports six successful cases treated by tapping with large trocar, after previous superficial incisions had been made. Through the canula a piece of lint was drawn to act after the manner of a drainage-tube. Notwithstanding such remarkable results, the puncture of an hepatic abscess with a large instrument, and regardless of existing adhesions, must be attended by great risk of the entrance of pus into the peritoneal cavity by the side of the canula.

In the light of our rapid progress in abdominal surgery, it becomes more and more evident that the proper treatment of hepatic abscesses, in which a tumor can be distinctly felt, is that by incision. Begin, as a preliminary step, first cut through the abdominal wall down to the peritoneum, and procured its adhesion to the underlying liver. Volkman, in cases of hydatid cysts, analogous so far as their therapy is concerned, goes one step farther—divides the parietal peritoneum and dresses the wound and surface of the liver with antiseptic materials, until, in the course of several days, adhesion to the margin of the wound is obtained. With the value of antiseptic treatment still *subjudice*, and the questionable control exercised over the extent of inflammation produced, it is doubtful whether this method will hold its own by the side of that adopted in the above case.

At the recent meeting of the International Medical Congress, Lawson Tait referred to five operations for hydatids, and one abscess of the liver, treated after the method of Sims' operation of cholecystotomy, without one fatal issue.

The operation practised in this case was unattended by the loss of even a drop of blood. The incisions through the abdominal wall and liver were made with the thermo-cautery. Hemorrhage from the divided liver-substance does, at times, prove alarming. By means of the thermo-cautery, this danger is avoided, as well as that of purulent infection largely decreased. With it a large incision can be made, inspection of the cavity with reflected light or laryngoscopic mirror, and the removal of large sloughs rendered feasible.

It will be seen that Listerism was not resorted to. That it is by no means an essential of success has been well established. Is it even called for when a wound can be so thoroughly irrigated as in the above case, and the material that could produce infection is removed as fast as it is formed?

Dr. Patrick Heron Watson has been appointed one of the Surgeons in Ordinary to the Queen in Scotland, in the room of Professor Spence, deceased.

LOCALIZATION OF INTESTINAL CATARRH.

A Contribution to the Diagnosis, with some Remarks on the Treatment of the Same.

By HUGO ENGEL, A.M., M.D.,

PHILADELPHIA, PA.

FELLOW OF THE AMERICAN ACADEMY OF MEDICINE, ETC., ETC.

There has in general very little attention been paid to the localization of intestinal catarrh. In fact there is only one chronic catarrh of the intestines recognized. We have been satisfied to give to abnormal discharges from the bowels, if they are not caused by some other disease, and if no other general or local origin can be detected, the name of "chronic catarrh of the bowels." But, as regards treatment, it is of great value to be able to localize such catarrhal conditions. Nothnagel was the first to give this subject special attention, and his work, recently published,[1] especially stimulated me to continue my own studies in this direction. Concerning Nothnagel's observations, they were made mainly with the view of ascertaining the alterations in the discharges, while I noted specially other symptoms and signs by which a differential diagnosis in regard to the localization of this ailment might be made.

In these diseases the same rule holds good as in all others. The more correct our diagnosis, the more exact we are in our localization of the malady, and the deeper our knowledge of the morbid process involved; or, in other words, the less we leave to uncertainty, imagination, and speculation, the greater will be the improvement in our therapeutics, and the surer will be our success in treatment. Only in such a manner will we be able to find the limits of the action of remedies; to foresee in all cases, with an ever-increasing certainty, the effect of our therapeutical measures, and to remove any symptoms with the same directness as we can now prevent a febrile seizure of intermittent fever with quinine, lock up the bowels with opium, or cause vomiting with tartar emetic, or sweating with pilocarpia. I do not by any means intend to convey here the meaning that we should ever forget, in a given case, the general scientific treatment, based upon a thorough knowledge of the constitution of the individual, as well as of the whole morbid process underlying and forming the disease in all its bearings and complications, but I contend that it is frequently of great importance, while not leaving out of view the general treatment of the case, which always will be the main point, to possess the means to remove, if possible, any disagreeable symptoms, which are often the most annoying to the patient. In certain forms of cancer, for instance, where we cannot think for a moment of a cure, it must not alone be our object to prolong life, but also to make the latter as tolerable as possible. While, in some kinds of bowel-complaints we try, for a considerable time, our best to radically cure the cause of the morbid condition, we may as well in the meantime endeavor to remove the disagreeable pains, the annoying tenesmus, and the frequent discharges, till at last these cease by themselves by the cure of the ailment which produced them. To be able, however, to bring about the disappearance of any such symptom, we must have the means of doing so, and we can gain the latter only by making a diagnosis always as accurately as possible, and carefully noting the action of the remedies in each special case. To assist in achieving this important result in chronic catarrhal inflammation of the bowels is the object of the following communication.

There are different signs and symptoms by which we may know the locality affected in chronic intestinal catarrh. We gain the necessary information mainly from the following sources: appearance and condition of the discharges, nature of the pain, general constitutional affection, the presence or absence of nausea and vomiting, the original cause, the appearance of blood in the stools and its character, the secretion of the urine, the effect on the general nutrition of the body, and the condition of the skin.

To understand fully the morbid alterations in the discharges, as they are dependent upon the seat of the lesion as investigated by Nothnagel, we have to remember only the difference in the functions of the small and of the large bowels.

While bile, pancreatic and intestinal juice are the main fluids poured out for the purposes of digestion into the upper part of the small intestines, albuminous matter that escaped the stomach, starchy and saccharine substances not before changed by the saliva, and all fatty and oily material are acted upon mainly in this same upper segment. In an affection of this part of the intestinal canal such articles of nutrition will appear more or less undigested in the discharges, especially muscular portions of meat. In the lower segment of the small intestines, near the iliac valve, the contents are kept back to allow the absorption of nutritive material, which if not properly taken out here in consequence of a catarrhal condition of the parts, will become changed in character, be more fluid, of a more yellowish color, and mostly more acrid. In the large bowel hardly any chemical action and comparatively little absorption is going on, but here the fæces receive their ultimate color and form, both of which will suffer alteration if there is any disease in that part of the bowel present.

We will investigate now the alteration in the stools. The discharge of mucus only, without any admixture of fæces, generally indicates catarrh of the rectum, but the mucus might in such cases be also derived from the sigmoid flexure or the lower part of the descending colon. But even in severe chronic catarrh of the rectum and descending colon, with greatly augmented secretion of mucus, the fæces need not always be covered by the latter, *i.e.*, we would be wrong in excluding chronic catarrh of the lower segment of the large intestine simply, because there is no mucus to be found around the scybala. Hyaline, mucous granules, recognizable by the microscope only, and intimately mixed with the solid or pappy fæces, but without microscopically visible mucus, indicate catarrh of the upper large intestine, respectively of the small intestine, but without participation of the lower segment of the former. Small yellow mucous granules in the stools denote affection of the small intestines. If the stools, or only one part of them, give the typical bile-pigment reaction, we may form the conclusion of the existence of a pathological peristaltic in the whole large intestine and in the lower part of the small intestine, and according to the other conditions of the parts giving this reaction—containing small yellow mucous granules or not—we may suppose catarrh of the small intestine, or only augmented peristaltic motion. Epithelium colored by bile-pigment de-

[1] Zur Klinik der Darmkrankheiten, Jena, 1882. Zeitsch. f. Klin. Med., iv., 1, 2.

notes catarrh of the small intestine and indicates, at the same time, a rapid locomotion of the contents throughout the whole intestinal canal; the same may be concluded from the appearance of round cells colored yellowish by bile, and of yellow-stained oil-globules. When high fever is present the appearance in the stools of many muscular portions of meat, partly undigested, does not permit of any conclusion with reference to an intestinal affection. Abnormal quantities of muscular tissue may appear without fever, and without any affection of the bowels, whenever, from any cause, the peristaltic motion of the intestines is increased. And even if catarrh of the small intestine exists, the muscular tissue need not be augmented in quantity as long as the frequency of the stools is not increased. But if with absence of fever, certain signs (mucus, etc.) indicate existing catarrh, and then, at the same time, abnormal quantities of undigested muscular tissue are present in the fæces, we are justified in concluding, from their presence alone, that catarrh of the small intestines probably exists. The presence of starch in the stools has the same diagnostic importance regarding the localization of the processes. The anatomical change by itself, caused by the catarrh, does not produce any increase of fat in the stools. If accompanying a catarrh of the bowels the quantity of fat in the fæces is morbidly augmented, it would simply denote a coexisting increase of peristaltic motion.

As regards auscultation, it is of no value in bowel-complaints of catarrhal nature. We are not able to judge from the different noises, from their character, or from their seat, either the locality of the affection or the nature of the same. A noise heard over a part of the small intestine would not justify us in concluding that it had its origin there, as the sounds are easily transmitted from one locality to another, and never confined to the place that produced them. On the contrary, occasionally—when from other reasons the locality of the lesion is well known, conditions favoring the transmission of sound or diminishing the same, as hard fæces, great tympanitis, large quantities of fluids in the bowels—those gurgling and wheezing noises, generally heard by the ear over disturbed intestines, are clearer a distance away from the lesion than immediately over it. If very gentle, they are not spread so far and are more circumscribed, but they are then of no value. The same may be said of percussion in these lesions.

Concerning pain, the following indications may be relied upon: If the pain is of a griping character, the lesion is confined to the small intestines. If a person presses with his hands on the abdomen to ease the pain, this is also an indication of the same seat. Whenever the pain is confined to the neighborhood of the umbilicus, it invariably, *cæteris paribus*, indicates lesion of the small intestines; soreness is always felt immediately over the seat of its cause. If the abdomen is swollen without producing in the patient a sensation of fulness coming up to his throat, its cause is mostly confined to the small intestines, while the opposite should direct our attention mainly to the transverse colon as the probable seat of the morbid lesion. Certainly we always take it for granted that there is no other disease than "chronic catarrh of the bowels," the localization of which is the point in question. Constipation, either alone, or alternating with *small* fluid stools, or the latter by themselves, with localized pain over a sausage-shaped swelling, connected with soreness over the same, a feeling of fulness there, and fever, always indicate affection of the colon, generally of the cæcum—catarrhal typhlitis. Tenesmus and drawing pains, extending to the back and toward the anus, denote an affection of the descending colon, sigmoid flexure, or rectum. If the pain is relieved more by belching than by the escape of wind by the anus, the lesion is in the small intestine; the opposite is true of the large bowel. Great rumbling in the bowels, long-continued griping pains, gradually relieved by defecation, or by escape of wind, denote lesion of the large intestines; milder rumbling, the sensation of water running through the intestines, sharp, short, griping pains, suddenly relieved by escape of gas, either by belching or from anus, but generally becoming severer during defecation, and ceasing for a longer or shorter time immediately after, indicate affection of the small intestines.

Nausea and vomiting, especially the former, if present in chronic catarrh of the bowels, is mostly connected with lesions of the small intestine, and the same may be said of large, thin, yellowish stools, often acrid in character, and occasioning burning at the anus. A sickening sensation felt at the time the bowels are emptied of their thin fluid discharges, associated with a disagreeable, but not very severe griping pain, referred to the lower part of the middle of the abdomen, is one of the surest evidences of the existence of catarrh in the small intestines. And we may say, that the higher up in the intestines the seat of the catarrh, the more we are apt to note sympathetic irritation of the pneumogastric nerve and of the stomach. Inward fever, great thirst, and often a glazed or dry, usually however, a fiery red tongue, are often observed in catarrh of the small intestines. In catarrhal affections of the large bowel, there is commonly an absence of any constitutional symptoms, no nausea and no dry tongue. If pain is present here, it is apt to be more continuous and localized.

In the vast majority of cases, errors in diet disturb the small intestines, which also easily suffer in sympathy with other organs, while exposure to cold or infectious causes, will mostly seize as their prey either the large intestines or the lowest segment of the small. It is further worthy of notice that the large intestines do not suffer easily through sympathy with organs; *au contraire*, they are apt rather to draw others, especially the liver, into the morbid process they started.

If the fæces are streaked with blood, or the latter is intimately mixed with them, it is usually derived from the small intestine; the face has generally then a pale look, the pulse is rapid, and a feeling of warmth is experienced often at the seat of the bleeding. If the latter is abundant, there is great constitutional disturbance, the same as in all internal hemorrhages. Further, as a general rule, the blood is darker the higher up its source. And here I wish to mention, that it is by no means necessary for the blood to have been exposed to the action of the gastric juice to be black. In certain affections, where in consequence of impediment to the portal circulation, intestinal hemorrhages are apt to take place, the bile is usually altered in its pigment, and its influence is such as to impart a black color to any blood it has come in contact with in the upper part of the small intestines, *i.e.*, the blood must evidently have been fluid and just oozing out, to permit of the bile-coloring matter exerting this influence. Therefore black stools, owing their color to the admixture of altered blood and altered bile,

indicate the seat of the lesion to be in the small intestine, in its uppermost part. In hemorrhages from the large bowel, the blood generally accompanies the fæces in the form of coagula, or is of a light red color, which is especially the case in hemorrhage from piles.

Peculiar morbid alterations in the shape of the stools invariably are evidence of the disturbance existing in the large intestines.

As regards morbid changes in the secretion of urine, we can only say, with reference to chronic catarrh of the bowels, that the higher up in the canal the lesion, the less is the secretion disturbed; there is generally increased flow, if any alteration, while in affections of the lowest part of the small intestines or in lesions of the large bowel there is apt to be diminished secretion.

As a great part of digestion and absorption of nutritive material is carried on in the small intestines, a chronic inflammatory condition there will produce more decided emaciation in a shorter time than the same lesion in the large bowels. When a diarrhœa is said to have caused, with a remarkable rapidity, a decided loss of strength and weight, we can take it for granted that, *cæteris paribus*, we have to look for its cause in the small, and not in the large intestines.

There is still another point which will be of value in localizing the catarrh. When a person is affected with chronic catarrh of the bowels and an eruption breaks out on his skin, if only herpes at the lips, we may be almost certain that the lesion is confined to the small intestines. The same may be said of any form of stomatitis, if not caused by a morbid condition of the stomach alone or from local reasons, and if accompanied by chronic intestinal catarrh. If the seat of the latter is in the large bowel it will never give rise to any stomatitis.

And what is the importance of knowing, in a case of chronic catarrh of the bowels, which part of the intestines is the one affected? We will endeavor to answer the question as well as we are able to do at present. In future, when more attention is paid to the localization of this complaint, the result of treatment will alone be sufficient to make this question appear a superfluous one.

If local abstraction of blood, or counter-irritation by a mustard-plaster, a fly-blister, or any similar substance, is deemed advisable, they should be performed as near as possible over the seat of the lesion. If we wish to empty the bowels of their contents, we should use rhubarb, calomel, or podophyllin, in affections of the small intestines, and aloes and clysmata in those of the large bowel. For antiphlogistic purposes and to keep the bowels in splint, very small doses of sulphate of sodium and morphia (the latter by the mouth or hypodermically), as well as soothing emulsions of almonds, with a moderate addition of aqua laurocerasi will be indicated in chronic catarrhal inflammation of the small intestines, while injections of tepid and cool water—large injections of the fluid containing small quantities of bicarbonate and chloride of sodium, carried by a long, flexible tube up to the place affected if possible—and combined with these, opium in the form of suppositories, will answer best in such lesions of the large bowel. If an astringent effect is wanted in the small intestines, acetate of lead, nitrate of silver, sulphate of copper, bismuth, tannic acid, and kino should be prescribed, while in the large bowel the same end would be reached with astringent suppositories. In case of serious alterations in the mucous membranes of the small intestines, brought about, perhaps, by a long continued catarrhal condition, we know of no better remedy than subnitrate of bismuth and sulphate of sodium, the latter in two-grain doses only, employed uninterruptedly for a long period, while in the same condition of the large bowel we must endeavor to make a local application with a solid stick of nitrate of silver, and administer internally minute doses of ipecacuanha, which seems to possess a great alterative power on the mucous membrane of this part of the intestines.

If we have reason to suspect, from the nature of the discharges and from other symptoms, a morbidly increased peristaltic motion in the intestinal canal, we must endeavor to check the same. And as the effect of this increase will mainly be felt in the small intestines, where it is especially harmful, as it prevents the absorbing vessels from feeding on the too rapidly propelled contents, we will best achieve this purpose of diminishing the increased motion by the internal administration of morphia, or by its hypodermic injection in the neighborhood of the umbilicus.

If, on the contrary, the peristaltic motion is too sluggish, if a kind of paresis has taken hold of the alimentary canal (a very frequent occurrence in chronic inflamed conditions of the bowels), the local application of faradic electricity near the umbilicus and hypodermic injections of strychnia in the same place will do for the small intestines what the introduction of one electrode of a faradic battery into the rectum and the application of the other electrode over the ascending colon will achieve with the same good success in the large bowel.

But another great benefit, we derive from our knowledge of the exact locality of this chronic intestinal catarrh will be found in the administration of the diet. In affections of the small intestines we must avoid those substances which are digested there, especially large pieces of albuminous and all fatty material. It is well known that in some forms of diarrhœa—as for instance, in the entero-colitis of children—milk, a strongly albuminous aliment, is not well borne; in the foregoing we find an explanation of this fact. Rice-water, burnt flour-soup, oatmeal-gruel strained through muslin, soup made from toasted bread, a little butter, salt, and water (the German *Wasser-Suppe*) must form the main diet in chronic inflammatory conditions of the small intestines, while in the large bowel we simply have to avoid all such nutritious substances which might assist in forming irritating solid and large fæces. Therefore any fluid diet will answer here, besides eggs, oysters, small quantities of raw meat, etc.

We often hear in chronic bowel complaints that what was beneficial in one case proved detrimental in another. It is only necessary to make an exact diagnosis of the locality in cases of chronic intestinal catarrh, and then to watch carefully the action of our remedies, and we will soon discover which of the latter have invariably a better effect on the small intestines, and which on the large bowel. We have here a wide field for future observations, which should especially be made in large clinics and dispensaries in large cities, during the hot summer months, when such catarrhs are more frequent than at any other time of the year. The result gained will fully repay the labor spent.

507 Franklin Street.

Reports of Hospitals.

CITY OF LONDON HOSPITAL FOR DISEASES OF CHEST, VICTORIA PARK.

SERVICE OF DR. THOROWGOOD.

(Notes by DR. LAWRANCE HUMPHREY, House Physician.)

PHTHISIS TREATED WITH ARSENIATE OF SODA.

ALFRED L——, plasterer, aged thirty-four, living in Bethnal Green, was admitted into the Victoria Park Hospital under Dr. Thorowgood, April 13, 1881. The family history was satisfactory, and patient had good health up to nine months ago, when he took cold from getting wet; this resulted in an attack of rheumatic fever, and as this passed away it left a severe cough for which he has been under treatment for the last three months. The patient is of dark complexion, and on admission complained of shortness of breath, loss of flesh, night-sweats, and severe cough with much thick blood, streaked expectoration. Latterly the cough has induced vomiting.

Urine, specific gravity 1016, high colored, no albumen, alkaline, and contains some excess of phosphates. Temperature, 100°. Appetite fair. Tongue furred posteriorly; edges red.

Below left clavicle there is a "crack-pot" note on percussion, with cavernous breath-sound, and large crepitant râles. Posteriorly, in upper left lung, crepitant sounds very distinct. Heart sounds normal, and apex *in situ*. Right lung marked by rough, prolonged expiration. Cough very severe, with much straining and vomiting. Ordered:

℞. Acid. hydrochloric.....dil. ♏vj.
Liquoris strychniæ ..... ♏iij.
Infusi calumbæ..... fl ℥j.
M. t. d. s.—Pil .extract. opii, gr. ¼ omn. nocte.

April 22d.—Still throws up food as much as ever. Cough bad and appetite failing; physical signs unchanged.

℞. Liq. sodæ arseniatis ..... ♏ij.
Infusi calumbæ. ..... fl ℥j.
M. t. d. s.—Pil. ipecac. c. scilla, gr. x. omn. nocte.

May 5th.—Cough keeps him awake. Still vomits, but crepital râles have notably diminished over left chest. Thinks medicine heats his stomach. Reduced dose of liq. sodæ arseniatis to ♏j.

May 12th.—Has not thrown up food for last five days. Phlegm much less and lost all trace of blood. Continued the same medicine up to May 27th, when, his time having expired, he went home, taking with him some cod-liver oil and a quinine and iron mixture. At his discharge he had nearly lost his cough, had good appetite, clean tongue. Pulse, 84; temperature, 98° to 99°; but he had not gained weight, and still had distinct râles with cavernous breath-sound in upper part of left lung.

REMARKS BY DR. THOROWGOOD.—After one week of the arseniate of soda treatment in this case, all agreed that the physical signs in the left lung seemed rather better. As the patient seemed doubtful as to whether the mixture suited his stomach, the dose of the liquor sodæ arseniatis was reduced from two minims to one minim in infus. calumbæ, and very soon we observed the vomiting to cease, the patient was able to leave his bed, and improved steadily and speedily. The improved digestion had not yet had time to manifest itself in an increase of weight.

Points worthy of note appear to be also, that during three months' treatment at a chest hospital prior to his admission, he had been getting gradually worse, and continued thus to get worse until he was put on the one minim doses of the arseniate solution. The rheumatic attack in the first instance, the catarrhal origin of the lung disease, and the marked implication of the stomach, are all indicative of an arsenical preparation as being very well worthy of trial.

In chronic bronchitis, with vomiting, two minim doses of liquor arseniatis have proved, in Dr. Thorowgood's hands, eminently curative in numerous instances, and these cures have, for the most part, stood well for many months, and some for over two years, after which period no further information has been obtained.

Progress of Medical Science.

SIMPLE TREATMENT OF EXCESSIVE SWEATING.—Dr. T. H. Currie, of Lebanon, says, in the *Michigan Med. News*: "For over thirty years I have used the following prescription, without a single failure, in sweats from whatever cause: Alcohol, O. j.; sulphate of quinine, ʒ j. Wet a small sponge with it and bathe the body and limbs, a small surface at a time, care being taken not to expose the body to a draught of air in doing it. In one case, a neighboring physician was poisoned while dressing a mortified finger. He suffered untold misery, and was drenched with perspiration for a number of days, and his life despaired of. When I saw him, I ordered him to be bathed immediately in the above solution, and that this be repeated once in two hours. The third application stopped all perspiration, and convalescence began at once."

TREATMENT OF FACIAL ERYSIPELAS BY SCARIFICATIONS AND OPIUM.—Dr. V. Netzetzky, of Russia, describes (*Vracheb. Vedom.*, No. 11, 1882) a treatment of erysipelas successfully practised by native barbers, and consisting in numerous superficial vertical scarifications made by a razor over the whole diseased part. After the bleeding spontaneously stops, they moisten the affected surface by an aqueous solution of opium (two grains to the drachm), and cover with a layer of cotton-wool. Rapid cure follows, as the author alleges; he himself observed two cases successfully treated in this way.

DIAGNOSTIC SIGNIFICATION OF THE ALVEOLAR EPITHELIUM OF THE LUNG IN SPUTUM.—The large granular epithelium that appears in sputum, Bizzozero considers undoubtedly proceeds from the alveoli (*Centralb. für Klin. Med.*, p. 529, 1881). He recalls the fact that in the alveoli there are two distinct kinds of epithelium, viz.: broad squamæ, and smaller, but thicker, and more granular cells. It is the latter class that undergoes rapid proliferation in inflammation, the other remaining unaltered. And it is the latter class that appears in the sputum. When present in large quantity in abundant sputum, they form a bad symptom, as indicating a general catarrh of the alveoli, but if in small quantity, they have no significance.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place, N. Y.

New York, September 2, 1882.

THE DECREASE IN DEATHS FROM CHILDBIRTH.

It is just a hundred years since the expectation of life among English women became equal, for insurance purposes, to that of men. Prior to 1772 women were compelled to pay an extra charge. At present the female expectation of life is about three years in advance of that of males.

A great factor in this prolongation of life is undoubtedly the increased knowledge and skill as regards the management of pregnancy and childbirth. There is hardly any progress in the past century which can be contemplated with such deep satisfaction as this diminished mortality rate.

Some figures recently collected by Dr. E. H. Sieveking may here be cited in illustration:

The mortality of lying-in women in London was, in 1660 to 1680, 1 death to 44; 1700 to 1740, 1 death to 70; 1760 to 1780, 1 death to 82.

In the Hotel Dieu, Paris, in 1786, it was 1 in 15.

At the beginning of the century the hospital mortality declined very much, while the total mortality also became considerably less.

In Prussia, in 1817, it was 1 in 112. In the whole city of London, during the years 1780 to 1820, it was 1 in 108.5.

From this time there has been an almost steady decrease in the death-rate of parturient women. This may be shown by a table compiled from statistics given by Sir James Simpson and Dr. Farr:

Years.	Proportion of maternal deaths in childbed: England and Wales.
1839	1 in 169
1840	1 in 168
1841	1 in 170
1842	1 in 192
1847	1 in 166
1851	1 in 192
1881	1 in 263

A distinction has to be made between the mortality rate of primiparæ and multiparæ. Among 36,776 cases collected by Hardy and McClintock, Matthews Duncan and Johnson, and Sinclair, the ratio of deaths among primiparæ was 1 in 62; among multiparæ, 1 in 124. This is certainly too high a rate, however, to represent the present state of affairs.

We can say now that whereas one hundred years ago 1 mother out of every 80 died in childbed, at the present time only 1 in 260 to 270 fails to survive. Obstetricians, midwives, sanitarians, all lay some claim to this prodigious advance in the saving of life. No single class or single influence, however, can be considered to have special and exclusive merit. Much is due to the advance in general knowledge and intelligence. More is due to the medical profession, undoubtedly, than to any other one agency.

SHALL THE TRAVELLING MESMERIZER BE ABOLISHED?

A new and curious medico-legal question has recently been raised in the Swiss courts, an account of which is given in the *Correspondenz-Blatt*.

In 1880–81 a famous "magnetizer," Donato, travelled through Switzerland giving exhibitions. One of the results was the development of a *furor* for mesmerizing each other, especially among the young people. In July, 1881, a young girl applied for admission to the Maternity Hospital at Berne, saying that she was pregnant. She stated further that being visited by a young man one evening, he mesmerized her and then violated her person. She was delivered of a child in September. Her story reached the ears of the "juge d'instruction" of Berne. He caused the matter to be investigated. Dr. Ladame, of Neuchatel, was appointed to investigate the matter. He did so, and gave a very elaborate report thereon. The question is, he says, an entirely new one in medical jurisprudence. There exist only four cases reported in medical literature.

These four cases are cited at length by Dr. Ladame, with the opinions of experts given upon them at the time. In one case the plea was asserted to be a fraud, because the woman was able to give a full account of the affair. This, in all cases, it was agreed, showed that the state produced could not have been a hypnotic one.

The other cases showed that violation could take place during "nervous sleep" without the knowledge and against the desire of the woman.

This opinion, sustained by Tardieu, Brouardel, and others, is one which would naturally be drawn from the known characteristics of this peculiar condition; and it may become a matter of importance in the future that this fact be known to medical men. The question will at once follow whether travelling mesmerizers should not be forbidden to exercise their arts. The influence which they exert upon the

health of their subjects is certainly not good. Should it become known that mesmerizing is a simple thing, and that a certain per cent. of young women are susceptible to the hypnotic condition, bad results to morals might follow.

On the other hand, the plea that violation was done by the help of mesmeric practices will almost always be difficult to prove. Dr. Brouardel, indeed, asserts that since the researches of Charcot it is possible to distinguish absolutely the hypnotic condition from simulation. This view is not, however, as yet generally accepted.

We trust that the subject may continue as rare and novel as it is now, though this can hardly be expected.

BORO-GLYCERIDE.

A SOMEWHAT sensational article has been going the rounds regarding the remarkable preservative and antiseptic properties of a substance called boro glyceride. Professor Barff first described its properties in a paper read before the Society of Arts, London. This gentleman stated that fresh meat soaked in boro-glyceride, then dried in the sun and packed in casks, was sent from the Falkland Islands to England uninjured. Oysters were preserved for three months. Pigeons and beef were kept for seven months, and were then made into pie with eggs that had been kept for six months. Milk and cream were also kept for a long time. The preserving fluid has very little if any taste. A number of other experiments showing its powers were cited.

In a paper recently read before the Kings County Pharmaceutical Society, Mr. Thomas D. McElhenie gives the details of the preparation of the new compound and also relates some experiments showing its power as a disinfectant. He states with justice that if it has the remarkable properties claimed, there will soon be a demand for the article by surgeons. Neither glycerine or boracic acid has the preservative powers attributed to their compound, which is made as follows:

Ninety-two parts of pure glycerine are heated to about 300° F., and sixty-two parts of boracic acid are gradually added. Steam is given off, owing to the water which is formed and set free. The operation, in quantities of five pounds or more, requires about a day to complete, as the viscidity of the melted mass allows the steam to bubble out very slowly. It is known to be finished when it ceases to lose weight and dissolves freely in water at ordinary temperature.

The product is solid, brittle, and transparent when cool, has a light amber color, and a shining fracture. It is freely soluble in warm water. It is sparingly soluble in cold alcohol, and in five parts of the same at 120°. It is insoluble in ether and chloroform at ordinary temperature. The hot alcoholic solution will, says Mr. McElhenie, probably be found an excellent means of impregnating absorbent cotton with boro-glyceride for surgical use.

If boro-glyceride be melted and an equal weight of glycerine added, a dense, clear mixture is obtained, which remains fluid on cooling, and is a very convenient form for many uses, being fifty per cent. by weight of the antiseptic.

The five per cent. solution is not affected by tannin, tincture of chloride of iron, Monsel's solution, or the mineral acids. These points, it is suggested may prove useful in treating diphtheria, when an antiseptic spray is employed.

As regards its preservative powers, Mr. McElhenie found that two eggs mixed with ʒ ij. of the ten per cent. solution were still good at the end of a month. The juice of two pounds of beef was kept fresh by ʒ ss. of the boro-glyceride.

The statements about this substance are very much like those which were made regarding salicylic acid when that drug was first introduced. Boro-glyceride, we are told, is less injurious and has little taste; but it remains to be shown that meat soaked for months in it can still continue palatable.

As regards its antiseptic properties and usefulness in surgical dressings there is no reason to doubt that it will be serviceable. Boracic acid alone is known to be a valuable agent for the surgeon. There can result no harm in the profession's testing the value of a substance which seems at least to be innocuous.

PRE-NATAL EDUCATION AGAIN.

DR. FRANKLIN C. CLARK makes an attempt, in the Report of the State Board of Health of Rhode Island, to treat seriously the subject of pre-natal education. His article has the merit of briefness, and it contains some truths, which, even if already known, cannot be too often repeated.

It has been a theory with lazy educators, and easy-going parents, that children will grow up as nature made them, and that their adult character is essentially a congenital affair. No doubt there are many children with but little plasticity. But it is the conclusion of the best scientists, that each generation has great power over the acquired as well as natural gifts of that which follows. The late Mr. Carlyle used oracularly to say "Man is a fingent plastic."

How best to increase this power over the succeeding generation is one of the problems of the modern educators. According to Dr. Clark, some educating influence can be exerted before birth. His conclusions, which are not very rich in practical suggestion, may be quoted here. After citing some familiar facts regarding heredity, he says:

That education may be of two kinds, namely, before birth and after birth.

That maternal influences exercise control over

the unborn child from their close relation with heredity.

That a perfect understanding of the laws of heredity leads to the proper kind of pre-natal education to be adopted.

That previous education of both parents, especially of the mother, makes the pre-natal education more easily moulded to hereditary tendencies.

That a careful attention to the mother during gestation is followed by the most happy results.

That the creation of tendencies, or predispositions, is all that in the present state of science can be expected.

How much can really be done to affect the child *in utero* is a point discussed at some length by our author, but we confess that he throws very little light upon it. It is generally conceded that powerful and prolonged mental and physical impressions exerted upon the pregnant mother will affect the offspring. There is no doubt that it is better for her to live a quiet and easy life. But that special agencies used upon the mother can produce special effects upon the child is certainly not true except in the rarest cases. And so far all historical studies and medical experience show little more as regards pre-natal education, than that the mother should be placed in good hygienic surroundings with as little physical work or mental worry as possible.

TRUMPED-UP LUNACY.

According to statements made in the daily press, there have recently been three cases of sane persons wrongly imprisoned in insane asylums. The most notorious of these is that of a lawyer, living in Yonkers, who was taken to the Utica Insane Asylum, and detained there for about three months. He was then removed by order of the court, the judge avowing, when the discharge was given, that the patient was not and never had been insane. The story of Mr. Silkman's experience in the asylum runs through three columns of the New York *Herald*, and is most affecting, if true. He states that, owing to certain pecuniary and other difficulties with his son, that young man arranged a conspiracy for his imprisonment.

Mr. Silkman is sixty-two years of age, and of an emotional temperament. He had recently joined the Land League, and was a warm advocate of the Irish cause, which fact was one of the evidences of his insanity. He states that his mental condition was examined into by only one physician, who saw him for but five minutes. The other signer of the certificate did not see him at all, nor did the judge. When at Utica his trials were very great. He had poor food, poor quarters, menial work, and harsh treatment. The sufferer's denunciations of Dr. Gray are very bitter. He was taken finally to the Middletown Asylum, which he praises highly. In contradiction to the opinion of the Utica authorities, he was here pronounced sane.

Mr. Silkman's story of his asylum life is exaggerated, and in some details manifestly untrue. Any one reading it carefully would think it not impossible that the narrator should have been insane. There are, however, stronger evidences here of mistake or foul play than is usually the case in newspaper stories of this kind. The alleged irregularity in commitment and the disagreement in diagnosis among the asylum experts are particularly deserving of inquiry.

Whatever be the actual facts, we find in this and similar cases a strong argument for the more thorough supervision of asylums by a competent and trustworthy board of commissioners. If the public knew that such a board, in whom it had confidence, was regularly inspecting asylums, there would be fewer grievances and fewer necessary and unnecessary newspaper sensations.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 28, 1882.

Dr. E. C. Seguin, President, in the Chair.

Dr. Heineman presented specimens illustrating

MULTIPLE SARCOMA.

Garrett S——, aged forty-seven; Ireland; widower; rockman; was admitted to the Roosevelt Hospital May 8, 1882. Eight weeks ago he first noticed a tumor in the right parotid region, which has since grown rapidly but painlessly. Has not emaciated. On admission he had a tumor 4½ by 3½ inches in the right parotid region, firm in consistency, movable, and without adherent skin. There was also a tumor involving the outer third of the left clavicle, and the head of the left humerus. There was pain in left arm at times, and slight loss of power.

May 13th.—Had a chill. New tumors discovered. Has considerable pain at times.

June 15th.—Tumor of neck and tumors elsewhere increasing in size, and new ones are appearing. Gradually failing.

June 24th.—Died at 3.45 P.M.

Autopsy, made June 25, 1882.—Brain and cord were not examined (permission refused). The heart, liver, spleen, stomach, and intestines were normal, except slight catarrhal inflammation of the latter. The *lungs* contained a few yellowish tumors of the size of a pea. Surface of lung adherent in a few situations to the costal pleura and tumors of the ribs by firm adhesions. Lungs congested and œdematous. Kidneys contained a few pea-sized nodules. Large tumor of right parotid adherent to basis cranii and transverse processes of first and second cervical vertebræ, firm in consistency, yellowish white in color. Tumors, varying in size from a pea to a goose-egg, existed in the subcutaneous connective tissue. Tumors involving the ribs, of varying size and in different stages, the larger causing absorption of the bone. Tumors of the left clavicle and of the head of the left humerus; bone of the latter completely absorbed, only the shell of articular

surface left. The bronchial glands contained new growths. The cervical and lumbar glands were enlarged. There were tumors of the omentum.

Dr. Heineman remarked that the kidney in cases of retro-peritoneal tumors of this character was frequently apparently involved, but closer examination usually showed that the kidney structure was not invaded.

Dr. Carpenter had observed the same appearance in cases of retro-peritoneal growths.

TYPHUS FEVER—DIFFICULTY OF DIAGNOSIS.

Dr. W. M. Carpenter presented, in behalf of Dr. T. E. Satterthwaite, a number of microscopic slides, exhibiting the changes that had taken place in the heart, liver, and kidneys, in a case of typhus fever that occurred at the Presbyterian Hospital. The main facts were as follows:

Bridget R——, aged forty; married, and a native of Scotland; was admitted to the Presbyterian Hospital on May 4, 1882, at 5.35 P.M. Being delirious at that time no intelligent statements were obtained, but it was learned that a physician had visited her at her home and, it was said, had treated her for a fracture of the ribs, which she claimed to have sustained from falling against a stove. Pleurisy was also said to have resulted from the fractures.

Subsequent facts threw doubt on this story, which emanated from some of her friends; for it was found later in the history of the case that shortly before admission to the hospital she had moved from a house in East Forty-seventh Street (possibly from one of the now famous nests of typhus, Nos. 335 and 337), where there had been sixteen cases and two deaths.

The patient was carried into the hospital on a stretcher. Pulse, 142; respiration, 36; temperature, 103¾° F. There was a slight dusky eruption on the chest. Urine albuminous. Patient refused most of the nourishment that was offered her. Soon became comatose and never regained her consciousness. No fracture of the ribs or pleuritic rubbing found on examination. On the following day (May 5th) an eruption was noted over the entire body. The variety seen in the anterior surface consisted of spots varying in size from a pin's head upward. Pulse now was barely perceptible. Temperature (axillary), M., 102½°; E., 104½° F. Death at 10.05 P.M., twenty-eight and a half hours after admission to the hospital.

Autopsical examination, sixty-four hours after death. Drs. T. E. Satterthwaite and W. H. Porter present. Body well nourished. Rigor mortis well marked. Dark purple eruption over the anterior surface of the trunk and extremities, not disappearing on pressure; extensive post-mortem ecchymoses over the dependent portions of the body, the hands and feet excepted.

Thoracic cavity.—Pericardial sac contained three drachms of bloody fluids. Heart enlarged; weight, fourteen ounces; soft, flabby, and fatty. Ventricular walls thin. Valves free and sufficient, but the mitral showed evidence of fatty degeneration, and the upper margins of Valsalva's sinuses were marked by fatty or calcareous changes. Post-mortem staining of all valves and of the aorta.

Right lung.—Free from adhesions. Hypostatic œdema. Weight, twenty-six ounces. *Left lung.*—Lower lobe adherent to chest-wall diaphragm by old pleuritic adhesions. Hypostatic œdema. Weight, twenty-three ounces. No fracture of any rib, and no indication of recent pleurisy.

Abdominal cavity.—Spleen enlarged and almost diffluent. Weight, nineteen ounces.

Kidneys.—Right: Capsule somewhat thickened and adherent and fatty (parenchymatous change). Weight, eight ounces. *Left:* Contains evidences of an old cyst, but in other respects is similar to the right. Weight, nine ounces.

Liver.—Enlarged. Weight, sixty-nine ounces. Soft, fatty, and showing evidences of portal congestion.

Brain and meninges.—The latter contain more blood than usual; an abnormal amount of serum at the base.

Urine (drawn after death).—Sp. gr. 1,018. Albuminous and contains numerous coarsely and finely granular casts.

This case was chiefly interesting from a diagnostic point of view. The morbid lesions of typhus are, however, known to have no pathognomonic features. The autopsical revelations were, briefly, a general softening of internal organs, with an enlargement and softening of the spleen, an abnormal transudation of fluids into the tissues and cavities, a dark purple rupture that did not disappear at death, and the renal changes of chronic nephritis. As the coma and rapid rise of temperature, with the other phenomena, could not be explained by uræmia alone, a further cause was sought for and found most naturally in typhus fever, which alone was competent to explain all. Accordingly this conclusion was stated to be "possible, if not probable." On the day following the obscurity was removed from the history of the case by intelligence received from the Board of Health, that a patient of the same name had decamped from East Forty-seventh Street, and after much search had been traced to the Presbyterian Hospital. The origin of the disease then became clear.

Dr. J. C. Peters said that he was familiar with the situation and history of the houses from which the case came. He was of the opinion that none of the cases of typhus occurring in the years 1881–82, in New York, had been traced to importation. The houses in question were overcrowded tenement houses, near the northern boundary of the slaughter-house district, and in the neighborhood of garbage and filth dumps, and at the same time a sewer emptied a cove at the foot of Forty-sixth Street. Every possible effort was made to improve the hygienic condition of the locality, but unsuccessfully, until finally the proprietors of a large malt-house and a number of butchers were appealed to, and by their aid the nuisance was suppressed.

THE TÆNIA MEDIO-CANELLATA, OR BEEF TAPEWORM.

Dr. Carpenter also presented, on behalf of Dr. Satterthwaite, two varieties of tapeworm, which had some special points of interest. Of one, the head exhibited on a microscopic slide showed it to be the tænia medio-canellata. It had been derived from a patient in private practice. This worm is probably more frequently found in the human body than has heretofore been supposed. It is the adult form of the *unarmed tapeworm*, being distinguished from the common armed tapeworm, the tænia solium, in that it has no hooklets at all, but merely four large suckers. Unlike the tænia solium, also, it has no rostellum. The central sucker described by Leuckardt was not seen. It is also interesting from another point of view, being the beef tapeworm, its measle or larval form existing in horned cattle chiefly, whereas the measle of the tænia solium is found in the hog. In either case the system becomes in-

fected by eating meat that is either raw or has been insufficiently cooked.

A NEW VARIETY OF BOTHRIOCEPHALUS.

Specimens were then exhibited of an adult *bothriocephalus;* they had been taken from the intestinal canal of a large python that died in the Central Park menagerie. The animal had suffered from *gangræna oris* so commonly observed in this species of reptile, and its death was ascribed to the septicæmia which would naturally be the accompaniment to such a disease. This particular species of bothriocephalus had apparently not yet received a name, and accordingly it was intended to have it properly and fully described in the near future. Its peculiarity consisted mainly in the shape of the head, which was double, each division being marked by a central depression. It had neither hooks nor suckers and the segments were incompletely separated.

Dr. Carpenter also presented a fresh specimen of probable

MYXOFIBROMA OF THE NARES,

for which he was indebted to Dr. Wm. C. Jarvis, who removed the growth and furnished the following notes of the case: The patient, a gentleman twenty-seven years of age, was referred to him by Dr. L. Weber. Anterior rhinoscopy showed the nostril to be stenosed by gelatinous polypi. The posterior nares were found to be obstructed by a large irregular growth, the posterior margin of which rested upon the soft palate. The upper border encroached upon the vault of the pharynx, extending beyond the pharyngeal tonsil. The entrance to the left Eustachian tube was concealed by the lateral margin of the tumor, but the posterior outline of the right Eustachian eminence was visible. The growth, as reflected in the rhinoscopic mirror, was of a light pink hue. It had a cartilaginous feel and gave a harsh graty sensation when scraped with the finger-nail. The growth extended forward into the left anterior nares, where it could be distinctly seen and seized. Pressure upon the anterior prolongation of the polypus produced a corresponding disturbance of its posterior portion. Immediate removal was recommended, and the operation was performed by means of Jarvis's wire ecraseur. No anæsthetic was used. A piece of No. 5 piano wire was carried through the anterior nares, sheathed in the canula, and projected around the growth. More than *five hours* were occupied in making gradual traction, the instrument bending like a bow under the strain to which it was subjected, and pulsating like an artery. Just before complete excision was reached, the wire snapped with a distinct report, having been cut by the sharp edges of the steel point screwed to the ecraseur's canula. No hemorrhage occurred. An attempt was made to draw the excised portion from the slight remaining attachment to the mass, but as considerable force was required, it was thought best to desist, for fear of starting a hemorrhage, and the tissue was allowed to slough off. The patient returned June 28th, several days after the first sitting, the portion first excised having disappeared, when a large wire loop was carried into the mouth through the naso-pharynx, and made to encircle the base of the growth. Three hours and a half were occupied in making slow traction, at the end of which time the polypus was removed, one portion of which was mucoid in appearance and very vascular, being covered with large vessels, and the other very dense. The only pain complained of, and then only during the second operation, was a severe toothache. Not a drop of blood trickled from the nose into the pharynx. The large sphacelated spot upon the surface of the mass indicated where nearly one-half the growth sloughed off after the incomplete section at the first operation. The nose was also cleared of the gelatinous polypi. The division of the tumor through its densest portion without pain and hemorrhage demonstrated a safe and easy method for removing large nasal fibroid tumors piecemeal, without resorting to the more formidable surgical operations. The specimen was referred to the Committee on Microscopy.

Dr. Wm. H. Porter, in behalf of Dr. George F. Shrady, presented a specimen of

OSTEO-SARCOMA OF THE FEMUR—CIRCULAR AMPUTATION —PERIOSTEAL FLAP.

The patient was a man twenty-four years of age, and of strumous diathesis, who had enjoyed a fair degree of health up to two years ago, when he began to suffer from some difficulty affecting the left knee, which was diagnosticated as synovitis by his attending physician, and he was treated for that disease for eight months. During this time the joint gradually enlarged and assumed an irregular globular shape, the enlargement being most marked over the external condyle of the femur. One year after the onset of the knee trouble, he was seen by a prominent surgeon in the city in which he lived, who diagnosticated advanced cancer of the knee-joint, and advised against all operative interference. When Dr. Shrady first saw the patient, two months ago, the tumor presented the appearance of a central sarcoma originating in the epiphysis of the femur. At that time the tumor could be distinctly outlined, was irregular in shape, and yielded a crackling sensation, and indistinct fluctuation on palpation. The veins running over the surface of the tumor were markedly enlarged. Diagnosis of central osteo-sarcoma was made, and immediate amputation of the thigh advised. On account of an attack of scarlet fever the operation was delayed two months. In the meantime the growth increased in size somewhat, but its general features remained unchanged. Amputation was performed by Dr. Shrady by the circular method, June 20, 1882, and the loss of blood did not exceed four ounces. The periosteal flap was made, the end of the bone being thus completely covered. The stump was dressed by introducing a drainage-tube on each side and then covering the whole firmly with sheets of carbolized gauze, which, up to date, eight days after the operation, had not been removed, and at no time had there been any acceleration of pulse or rise of temperature. The general condition of the patient had improved, and there was good prospect of recovery.[1]

The specimen was a typical one of its kind, had its origin in the cancellous structure of the external condyle, and was almost completely surrounded by a bony shell.

OSTEOMA OF THE PENIS.

Dr. Wm. H. Porter then presented a specimen of bone which he had removed from the penis, with the following history:

[1] The dressings were removed on the ninth day, when it was found that union by first intention had taken place, except in the track of the drainage-tube. The latter was removed, when the remaining parts healed within a few days.

J. T——, aged sixty-three, about two and one-half years ago accidentally noticed a small lump on the dorsal surface of the organ and to the right. At first the only trouble which it gave was the mental annoyance. Later on it enlarged slowly, causing pain and a slight deflection of the penis when erect. The neoplasm enlarged very slowly, and caused a comparatively small amount of pain, but great mental uneasiness. The growth was irregular in shape, broadest at the junction of the middle and posterior thirds, pointed anteriorly, where it was united with the glands. It was freely movable under the skin.

Operation, July 15th.—A small opening was made directly over the tumor, and it was slipped out through a buttonhole opening. It was quite firmly attached to the fibrous tunic of the corpus cavernosa. The patient had done well, and was practically cured.

The mass, when freed from the adherent soft tissue, was found to be quite irregular in outline. It measured six centimetres in length and three centimetres at the widest point. It was slightly arched to fit the convexity of the penis.

Microscopic examination showed that it was a true bony mass, as it contained distinct lacunæ and canaliculi.

The case was certainly unique, if not the first of the kind recorded.

THE PRESIDENT had supposed that these growths were cartilaginous Some time ago a case came under his observation in which there was a distinct plate of resisting tissue about an inch and a half in length and half an inch wide, and situated apparently between the corpora cavernosa. He referred the patient to Dr. Keyes, who was unable to make any therapeutical suggestion.

DR. V. P. GIBNEY presented specimens with the following history:

OPENING OF SPINAL ABSCESS INTO A BRONCHUS—EXPECTORATION OF SEVEN PARTICLES OF BONE FROM CARIOUS VERTEBRÆ.

Many years ago, in the beginning of his service in the Hospital for the Ruptured and Crippled, he had a case of paraplegia from a high dorsal Potts, and the progress toward recovery, after so hopeless an outlook, made such an impression on his mind that he has always remembered, with much interest, Nellie L——, aged thirteen years, from an Eastern State, who was admitted to hospital, June 21, 1871, suffering from caries of the upper dorsal, the deformity of which was not great, but was seemingly of long standing. She seemed to have recovered from her caries, and within the preceding six months a relapse had come on, taking the form of a compression myelitis. For several months she had been growing weak in her limbs, and had been complaining of pains in her back. On admission, her gait was tottering, and her spine was tender. She was constipated, and had much difficulty in voiding her urine. A spinal support was applied and no notes of the reflexes recorded. On July 15th she was quite unable to stand, and during the following weeks she had great rachialgia, unrelieved by treatment. On July 30th paralysis in lower extremities was very nearly complete, and the feebleness of the grasp indicated a cervical paraparesis. In August she had retention of urine and catheterization was resorted to three times daily. She suffered much during that month from involuntary muscular spasms in inferior extremities. Blistering, followed by free poulticing, constituted a large part of the treatment. Her vesical paralysis did not continue longer than two or three weeks.

In May, 1872, she was walking by the aid of a chair. In December of same year she was walking alone, and by February, 1873, her restoration was complete. Shortly after this she was discharged cured. Four or five years later the report came to the hospital that she had died of consumption, and recently this report was contradicted. He wrote to her and received the following letter, which gives a very satisfactory history of the case to present date.

"DEAR DR. GIBNEY: . . . . First, I never have had any return of paralysis. My deformity has increased considerably; I have had two abscesses. A large swelling came on my right side, just inside my hip-bone, which was first called a rupture and then a fatty tumor, and in about a year and a half it came to a head and proved to be an abscess, and was lanced five years ago last September. A severe cold set in at the same time and the doctor thought I had quick consumption. I was very sick all winter, and the abscess discharged a great quantity of bloody matter. In the summer I got better, and was quite comfortable, until a year ago last winter, the left side of my back began to swell and my cough increased, and I raised great mouthfuls of bloody matter just as fast as I could spit it out. At this time, and within ten days, I raised seven little particles which my doctor thought were spinal bone. I have never raised any before or since. When my back was lanced, it discharged a great quantity of precisely the same looking matter as I had been raising, and my cough was relieved within ten minutes and I have never coughed as hard since. The first abscess healed about three months ago, and now seems perfectly sound. I think it will hardly be necessary for me to say that I am not in good sound health, as I have never been strong. . . . Will you please write again and let me know what you think of the particles of bone of which I spoke. Nearly every one laughed at the idea, and one of the doctors said, 'One could as well cough up their rubber boots as pieces of their backbone,' yet he did not try to explain what they were. I have lost two, one being the largest of all, but have five of them yet."

In response to a second letter she sent the five remaining particles, which are presented this evening. They are about the size of a pin's head and look exactly like the bits of *débris* resulting from a caries necrotica, such as one finds in old caseous sacs, and such as I have, on more than one occasion, seen discharged from the openings of psoas abscesses.

DR. W. H. PORTER, Chairman of the

COMMITTEE ON MICROSCOPY,

reported that the tumor of the stomach presented by Dr. Messenger was a *colloid cancer*.

The Society then went into executive session.

A PLAGUE OF MEASLES IN ICELAND.—Two winters of uncommon severity, followed by cold summers, have practically destroyed the hay and grain crops in the north and west of Iceland, causing a great loss of live stock and bringing the people face to face with actual starvation. A chilling visitation of Greenland drift ice has greatly injured all vegetation during the present summer, and to add to the general despair, a plague of measles of a malignant character has recently descended upon the famine-stricken region. An appeal for help is made to this country.

Correspondence.

LANGENBECK'S LAST CLINIC.

To the Editor of The Medical Record.

Sir: The formal leave-taking of Professor von Langenbeck, which occurred to-day, has excited great interest in all circles of society, both professional and laic, and has elicited a most hearty expression of the admiration and esteem which is here universally accorded to him. And, indeed, Berlin may well mourn the departure of this Nestor among surgeons, who has now passed thirty-four years of his brilliant professional life in her midst, and who departs now only when the inevitable ravages of time remind him that his race is well-nigh run, and cause his enfeebled body to crave repose and comparative seclusion from the turmoil and anxiety which pertain to his exalted position in this great city. No surgeon in all Germany has better fitted himself for lasting remembrance as one of the brightest lights in the surgical world of the nineteenth century; and no one, with the possible exception of Volkmann, in Halle, occupies so high a place in the esteem of his professional brethren.

This morning the clinical assistants of Professor von Langenbeck repaired to his residence, and there presented him with a costly flower and fruit stand of solid silver, which was embellished with the Langenbeck escutcheon, and those of the cities Kiel and Berlin; while on its top it bore a statuette of Æsculapius. In the afternoon the spacious and handsome amphitheatre in the University Clinical Hospital presented quite an unusual aspect. The operating-table, with its snow-white cover, which generally occupies the centre of the room, had disappeared; as had, too, the tables, with their wonted array of dressings, knives, saws, forceps, etc. In their stead were substituted flowers and garlands, while a whole forest of palms filled in the back-ground, and combined with the rich and heavy festoons of laurel, pendant from the central chandelier, to render the interior charmingly pretty and attractive. Another innovation was the presence of two plaster-of-Paris busts, one on either side of the proscenium arch; on the left, that of the first director of the surgical clinic, Karl Friedrich von Graefe, the father of the celebrated oculist, and on the right, the ivy-decked bust of the then-departing Privy Councillor von Langenbeck. Long before two o'clock, the hour for the clinic, the interior of the hall was crowded. Students and staff-physicians filled the rows of seats; while below, in the operating space, were assembled the most prominent members of the medical and surgical world of Berlin, conspicuous among whom were the officers and members of the Berlin Medical Society. Scarcely had the academical quarter of-an-hour elapsed when Dr. Langenbeck appeared, in company with his assistant-surgeons—all in their long white linen operating-coats, and was received with quite a stormy ovation. When he essayed, however, to proceed with the regular business of the hour, he was interrupted by Professor Bardeleben, who, acting in the capacity of spokesman for the delegation from the Berlin Medical Society, expressed, in eloquent language, the high appreciation in which von Langenbeck was held by them all, and their exceeding sorrow that he should feel called upon to retire from the active pursuit of his profession in their midst. After referring with regret to the fact that the non-completion of a marble bust of the retiring surgeon, which was being executed by Siemering, rendered necessary the temporary substitution of that in plaster, Bardeleben concluded with a heartfelt, "Gott segne Sie auf Ihren weiteren Lebenswegen!" Visibly struggling with the emotion which threatened to o'erpower him, Langenbeck thanked his colleagues and hearers for their thoughtful attention, and excused himself for not appearing in festive attire on that occasion. "But," said he, "I've celebrated so many festivities in this place, when by difficult operations I've restored the sick and suffering to health and happiness, that this unsightly operating-coat seems to me a most fitting garb." He then referred to the great progress which the science of surgery had made during the forty-two years of his clinical professorship, thirty-four of which had been passed in Berlin, and congratulated himself on the fact that so many of their graduates had taken a conspicuous part in furthering this progress by their labors and investigations—instancing particularly Albrecht, Wagner, Bock, Wilhelm Busch, and Karl Hueter, who had already gone to their reward. As for himself, he said that he had always followed the conservative line in surgery, not merely cutting and amputating, but striving to conserve diseased members to the greatest possible extent, and to restore them again to usefulness. And, though the cases which he was about to exhibit would apparently contradict this statement and make it savor of grim irony, yet the course pursued had in each instance been unavoidable.

Thereupon, at his beck three beds were rolled in successively, each of which held a poor unfortunate upon whom Von Langenbeck had performed a hip-joint amputation within the last few days.

While the dressings were being removed, he proceeded to explain the method of operating employed by him, and demonstrated its effectiveness by exhibiting the beautifully clean and rapidly healing stumps. In conclusion, he wished his colleagues and hearers a hearty farewell, and expressed a hope that they might still be called upon to materially advance the progress of surgical science, and to afford healing and succor to many sufferers.

Mr. Heilcke then addressed a few fitting words to the revered instructor in behalf of the students, and these finished, Dr. Langenbeck pressed the hands of his friends silently but with fervor, and took his leave. At 2.30 the clinic ended. It was the shortest which Langenbeck had ever held in Berlin—it was his last!

Born on November 19, 1819, Professor Von Langenbeck is now in his sixty-third year, and his determination to retire into comparative inactivity at Wiesbaden, where he owns an elegant villa, is doubtless to be attributed in part to the fact that he feels his infirmities growing upon him. His hand trembles so that his writing is well-nigh illegible, but while operating it is perfectly under his control, and he makes his incisions with great nicety. In amputating at the hip-joint he first ligates the femoral artery high up. Then, without transfixing, but using his comparatively short "lappen-messer," he raises an anterior flap, which includes but little muscular tissue, and that only toward the completion of the section.

After securing all bleeding vessels, he next proceeds to merely outline the posterior flap. This done, he returns to the anterior incision, rapidly deepens this till the joint is reached, disarticulates

and completes the formation of the posterior flap. Two drainage-tubes are used—one in the retiring angle of the wound, which discharges at its inner extremity, while the other passes through the posterior flap and into the acetabulum.

The sutures now being inserted, the wound is dressed à la Lister, except that carbolized charpie, thickly dusted with iodoform, is substituted for the "protective." The wound is redressed after the lapse of twenty-four hours. This iodoform dressing is well-nigh universally employed by Von Langenbeck. Indeed, I remember no operation in which it was not used, either in the manner stated or, as in open resection wounds, directly applied to the raw surfaces. Still, I was informed by one of the clinical assistants that toxic effects are rarely met with, and then only in the event of large wounds being regularly dressed with the agent for long periods of time.

Von Langenbeck's successor, Professor Bergmann, of Würzburg, is a middle-aged man of forty-five (he was born December 14, 1836), and is the son-in-law of the well-known Russian State Councillor, Dr. Adelmann, of St. Petersburg. Only a few weeks since he was distinguished by the appointment as surgeon-general à la suite, in the German army, and, together with Gerhard and Kölliker, forms the principal attraction of the Würzburg medical faculty. After the completion of his medical studies, he connected himself with the Russo-Prussian university at Dorpat, where he was at first adjunct, and later regular professor of surgery.

In the surgical world Von Bergmann has become known through his exact and interesting studies of the septic properties of wound-secretions, and his experimental investigations into the pressure-symptoms sequent upon injuries of the cranium. Further, he has published studies on different operative procedures and their technical improvement—the result, in part, of his experience on the field during the Franco-German war. In his practice he is a firm advocate of Listerism. In the year 1871 he received a call to Königsberg as regular professor of surgery, and was preparing to accept the position when Dr. Schönborn was elected in his stead.

But in 1875, on the death of Professor Von Linhart, of Würzburg, Von Bergmann was appointed as his successor, and since that time he has occupied the chair of surgery, and has been director of the surgical division of the old and famous Julius Hospital in that town.

S. Y. Howell, M.A., M.D.

Berlin, July 21, 1882.

RETRO-PHARYNGEAL ABSCESS.

To the Editor of The Medical Record.

Sir: At the stated meeting of the New York Surgical Society, May 9, 1882, Dr. H. B. Sands gave an interesting account of a case of retro-pharyngeal abscess to which he had been called in consultation. From reading the published report of it in The Medical Record of July 22d I was clearly reminded of a case which occurred in my own practice in the winter of 1877–8, and which bore to it one or two striking points of similarity, while it differed from it very materially in others.

The patient was an illegitimate negro child, male, fairly nourished, about three months old, whose parents, as far as could be learned, were physically sound and free from syphilitic and scrofulous taint.

In the course of the first month or six weeks of its existence I had treated it successfully for *pemphigus*, in which the vesicles were chiefly confined to the dorsal surfaces of the hands and feet.

For several weeks thereafter the child was destined only to cope with the ordinary vicissitudes of infancy, besides being unusually neglected, when, succeeding a short premonitory period, a swelling developed in the neck on the left side, which after suitable time yielded distinct fluctuation, was promptly incised and evacuated of about half an ounce, or more, of muddy-looking pus.

Three days subsequently the incision had practically healed, the parts had reassumed their normal appearance, the child nursed well, and in all other respects seemed to have regained quite a satisfactory state of health.

In the morning, however, of the fourth day, or thereabouts, he was found to be feverish, fretful, and devoid of appetite. Investigation elicited the fact that the swelling in the neck was returning, and that the parts involved were sensitive to touch and painful on making the slightest movement of the head. As the readiest means at hand, fomentations and bread and milk poultices were ordered to be applied, and small doses of quinine administered at proper intervals.

The following night, when I saw him again, the constitutional disturbance had increased, and there was also some dyspnœa and difficult deglutition, accompanied by retraction of the head. He had refused all nourishment, and had been very restless and irritable throughout the livelong day.

I was able to make only an imperfect examination of the interior of the pharynx, but it was sufficient to convince me of a certain amount of tumefaction present in the left wall and median line, projecting somewhat into the cavity. Externally the intumescence was more prominent beneath and behind the sterno-mastoid muscle, and occupied the identical site of the former abscess, but extended to greater limits in every direction. The integument covering it was tense and shining, and obscure fluctuation was thought to be limited to a narrowly circumscribed area in the occipital division of the posterior triangular space.

Taking note of the child's unfavorable surroundings, and appreciating the danger that might accrue either from the burrowing action of an abscess beneath the deep cervical fascia, or from its sudden eruption into the pharynx, I at once determined to operate.

A bistoury was passed into the swelling from without and made to penetrate the deep fascia, but with just the effect of producing a current of dark-colored blood. Whereupon a grooved director was introduced with a slight forward inclination and forced to a depth of at least two and three-fourths inches. The merest trace of pus-streaked blood followed this manœuvre, and although a pair of dressing forceps was afterward thrust in and withdrawn with blades open (Hilton's method) no further evidence of pus ensued. Altogether, not more than two and one-half ounces of dark, quickly coagulable venous blood were lost when the hemorrhage ceased spontaneously, and the child's condition forthwith became perceptibly improved. Both the bowels and bladder relaxed, and gave copious emission of their contents; his struggles ended and his cries became silenced.

Pads were arranged as securely as possible on either side of the incision, and a simple dressing of

carbolized oil used. He was then put to the breast and proceeded to nurse greedily.

The next morning I was considerably surprised, as well as relieved, to find that all systemic disorder had apparently subsided, and that not the remotest indication of tumefaction, either externally or internally, remained. The wound itself, upon removing the dressings, was seen to have become intimately united by primary adhesion, and would easily have escaped any cursory inspection.

He continued under observation eight or nine months longer, and, despite his unpropitious situation, sustained an excellent standard of bodily welfare for the whole of that time.

I have never satisfactorily determined in my mind the true character of the affection. It was not entirely impossible that it might have been a remarkable manifestation of latent scrofula. But remembering all the circumstances attendant upon its inception and dispersion, besides considering among other things the great infrequency with which symptoms of the scrofulous diathesis are, to say the least, so conspicuously exhibited in a subject so young, the most natural conclusion is that such in reality was not the case. On the other hand, if it were simply a purulent collection, as supposed, where was the pus in sufficient quantity, or what became of it so mysteriously and with such wholesome effect? The probability of its having been due to blood extravasation, serous infiltration, or even to a cystic growth, is contrary to the history given, and was not supported by the symptomatic indications nor by the results of the treatment pursued.

Finally, it was certainly not emphysematous in nature, although from the peculiar mode of its disappearance, it apparently "melted into air; into thin air."

LACHLAN TYLER, M.D.

WASHINGTON, D. C.

THE DANGER OF ADMINISTERING AN ANÆSTHETIC DURING OR IMMEDIATELY AFTER REPEATED DOSES OF MORPHIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I am inclined to think that Dr. John A. McKennon has not drawn quite correct conclusions from the treatment of his case of nephritic colic, mentioned in THE MEDICAL RECORD of July 29th, page 140. It is my opinion that the well-nigh fatal result was not entirely due, as he thought, to the increased effect of the morphia, which followed the supposed dislodgment of the calculus, and the sudden relief of pain; but that it was in consequence of the *inhalation of chloroform* while giving the morphia.

Let me relate a case to the point. I once had under my care a woman who suffered from severe uterine colic, not associated with menstruation or pregnancy. On the occasion referred to, she had taken twenty minims of tr. opii an hour previous to my arrival. As her suffering was still intense, I at once gave ¼ gr. morphia sulph. hypodermically. Waiting a half hour and astonished that the pain did not abate in the least, I repeated the injection, giving ¼ grain. Still there was no relief. A hot sitz bath was likewise fruitless. I waited an hour, and as her agony seemed almost intolerable, I administered hypodermically ½ grain fresh solution of morphia sulph. A half hour passed, and she still suffered as keenly as before. She received another ½ grain hypodermically, but without effect.

Within three hours she had received the equivalent of nearly two grains of morphia, so that I determined to abandon its use. The only resort I could think of to bring the prompt relief that was so urgently demanded was to suspend consciousness. Some of Squibb's ether was near, about two drachms of which I poured upon a small towel, and held to her nose.

It was not more than a minute when she ceased moaning. I at once removed the towel. In another minute she gave the same evidence of suffering, when I replaced the towel, having added about one drachm of the ether. Watching her very closely, with my finger on her pulse, I soon observed a change in her expression which led me to gently shake and speak to her. She did not respond.

Instantly, an ashy pallor overspread her face and respiration ceased. Her peril was imminent and obvious.

By the most vigorous slapping, thumping, and dashing of cold water in her face, I elicited a feeble response, which was finally fanned into consciousness.

In two hours she was out of danger, and I was intensely relieved. Two hypodermic injections of atropia sulph.—the first $\frac{1}{80}$ of a grain, given as early as possible, and the second soon after, $\frac{1}{60}$ of a grain—rendered invaluable service.

Even after such profound narcosis, the uterine neuralgia persisted, though not quite so severe, and was finally relieved by chloral hyd. and potassium bromide.

This taught me a lesson which I shall never forget, and I believe the same lesson is to be learned from Dr. McKennon's case.

In either case, without the use of the anæsthetics, I do not believe toxic symptoms would have supervened.

The explanation I would venture is, either that the anæsthetic renders the system greatly susceptible to the action of the morphia; or else, that the suspension of consciousness at once deprives the patient of that force which we know to be potent in resisting toxic or other depressing influences.

Be the explanation what it may, the effects are the same.

It would be interesting to have the experience of others with this narco-anæsthetic combination.

S. H., M.D.

PENNSYLVANIA.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 20, 1882, to August 26, 1882.

MURRAY, ROBERT, Colonel and Surgeon. Relieved from duty as Medical Director Military Division of the Missouri, and to report in person to the Commanding General Military Division of the Atlantic and Department of the East for duty as Medical Director of that division and department. S. O., 191, A. G. O., August 18, 1882.

BILL, J. H., Major and Surgeon. Granted leave of absence until December 1, 1882. S. O. 196, A. G. O., August 24, 1882.

ALDEN, C. H., Major and Surgeon. Granted leave of absence for three months. S. O. 196, C. S., A. G. O.

MUNN, C. E., Captain and Assistant Surgeon. The leave of absence granted him in S. O. 147, Department of Missouri, July 28, 1882, extended two months. S. O. 196, C. S., A. G. O.

SPENCER, WM. G., Captain and Assistant Surgeon. The leave of absence granted him in S. O. 80, April 7, 1882, from A. G. O., is extended two months. S. O. 191, C. S., A. G. O.

OWEN, JR., WM. O., 1st Lieutenant and Assistant Surgeon. Assigned to temporary duty at Vancouver Barracks, W. T. S. O. 114, Department of the Columbia, August 11, 1882.

MACAULEY, C. N. B., 1st Lieutenant and Assistant Surgeon. To report in person to the Commanding General Department of the East, for assignment to temporary duty. S. O. 192, A. G. O., August 19, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending August 26, 1882

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
August 19, 1882.	0	33	28	5	9	29	0	0
August 26, 1882.	1	29	29	5	9	45	0	0

MR. STOKES' ADDRESS.—In Mr. Stokes' address (p. 245), it is stated that a mortality of only 3 in 600 cases occurred. It should read three per cent. or strictly 3.6 per cent. On page 247, instead of Dr. Ashley, read Dr. Ashby.

NATIONAL BOARD OF HEALTH.—At its meeting, August 15th, Dr. Chas. Smart was elected secretary, in place of Dr. Turner resigned.

DR. AUSTIN FLINT will deliver the Philadelphia County Medical Society's lectures during the coming winter.

A NEW MEDICAL COLLEGE in London, Canada, has just been organized. London is a city of about 20,000 inhabitants, and now expects to have a hospital.

A BUST OF THE LATE PROFESSOR JOSEPH PANCOAST has been made, and will be presented to the Jefferson Medical Society.

THE LOWELL LECTURES.—Dr. W. B. Carpenter is to deliver the next Lowell lectures in Boston.

PRELIMINARY EXAMINATIONS FOR THE UNIVERSITY OF PENNSYLVANIA.—In order to facilitate the admission of students and to aid the upward tendency of medical education, the authorities of the University of Pennsylvania have appointed physicians, graduates of that school, in the different prominent cities of the Union, remote from Philadelphia, whose duty it shall be to examine candidates for admission into the Medical Department. The result of the examination is forwarded to the authorities of the University, who, in turn, notify the candidate of his success or failure. By this means the applicant is spared the expenditure of time and money necessary to a trip to Philadelphia on an uncertainty.

TWO NEW CASES OF RESECTION OF THE PYLORUS have recently been operated upon; the one by Gussenbauer, of Prague, the other by Bamberg.

THE PRIZES OF THE ACADEMY OF MEDICINE, of Paris, were bestowed at the annual meeting, August 1, 1882. Of the thirteen prizes offered only eleven were awarded. Among these, and of most interest to Americans, was the Prix d'Argenteuil of 10,000 francs, of which 6,000 francs were awarded to Dr. Henry J. Bigelow of Boston, author of a work entitled "The Cure and Prophylaxis of Strictures of the Urethra by '*Dilatation Urodyname;*'" 4,000 francs to Dr. The. Anger, of Paris, author of an essay describing a new thermo-cautery, and of an essay upon peno-scrotal hypospadias. We congratulate Dr. Bigelow upon thus atoning for the slipping away of the Boylston Prize.

Among other prizes awarded was the Prix Barbier, 6,000 francs, to Professor Toussaint, for his experimental studies in charbon, cholera of fowls, etc.

For the year 1883 the Academy offers seventeen prizes, the total amount of money being over 60,000 francs. The largest prize, that of M. and Mme. St. Paul, and amounting to 25,000 francs, will be given to any one who, in the judgment of the Academy, has found a remedy against diphtheria.

A SCIENTIFIC TUG.—The good ship Henrietta sailed into Galveston, Texas, in the first part of August, having on board several cases of reputed yellow fever. She was quarantined and a tug ordered by the city authorities to take her to Ship Island.

Her voyage should be a memorable one in sanitary annals, for it showed how quickly the untutored mind of the seaman seizes upon and applies the most recondite speculations of pathology. A despatch says: "One of the singular things connected with the affair was the mention of the alleged fact, based on the discovery of the late Dr. Chopin, that the yellow-fever germ travels forty feet a day. So, to make sure of saving the steam-tug from contagion on the way to Ship Island, a six hundred-foot hawser was purchased and used on the trip. The trip only occupied three days, so, of course, only one hundred and twenty feet of the hawser was infected and required to be burned."

THE AMERICAN ASSOCIATION OF SCIENCE held its annual meeting this year at Montreal, August 23d, 24th, and 25th, over six hundred members being present. The only papers which we find reported of medical interest were one by Dr. Warder on "Contamination of Wells," and a description by Professor Bell of his instrument for locating bullets in the human body.

DR. J. MARION SIMS, who was made a Chevalier of the Legion of Honor in 1864, as a reward for scientific merit, has, by decree of July 13th last, been made Officer of the Legion of Honor for services rendered as surgeon-in-chief of the Anglo-American Ambulance at the battle of Sedan.

A GERMAN SURGEON'S OPINION.—Professor Esmarch is reported as declaring that the surgical treatment of the late President Garfield was wrong, and that his life might have been saved by proper medical care. Esmarch lives a long way off, and speaks at a very late hour. It is easy to make mis-

takes under such conditions. He had better have held his peace. There are many American surgeons who know more than Professor Esmarch and think very differently from him.

Medical Registration in Pennsylvania is evidently well received. Of the 6,942 doctors in that State all but about 500 have registered.

Professor Esmarch's Work, "First Help to the Injured," has been translated into English by the Princess Helen of Great Britain. Professor Esmarch has aroused much discussion by his zealous encouragement of Samaritan Societies, which are organizations among the laity for the purpose of learning and teaching the way to meet medical and surgical emergencies. It is thought that a little knowledge is a dangerous thing, and that people will be encouraged by these societies to meddle more than they will be taught to help. Esmarch has finally written a letter to the *Allgemeine Medicinische Central-Zeitung* defending his views.

Progress of the Yellow Fever Epidemic.—Since our last note a complete sanitary cordon has been established from Laredo to Corpus Christi, by which the fever will probably be kept within the triangle of which these places and Brownsville form the angles. Fifty or sixty cases of yellow fever per day have been announced as occurring at Brownsville.

On August 28th a case of yellow fever was brought to Pensacola, Fla., on the bark Penang, from New Orleans.

Alleged Horrors of a Utah Insane Asylum.—Hon. G. A. Tucker, an English gentleman from New South Wales, accompanied by the United States Marshal Ireland and Mr. Neal, of Louisville, Ky., visited the Utah asylum recently, which is under the charge of Dr. Seymour B. Young, a nephew of Brigham Young, and three Mormon Commissioners. Mr. Tucker says he found twenty-one patients, nine females and twelve males, in the most filthy condition imaginable. Some were in iron cages outside the main building, while others were in irons, bound hand and foot.

A Case of Typhus Fever discovered in this city during the last part of August was found to have been imported from Cornwall by the patient, an Italian railroad laborer. Incidentally it is stated that this class of laborers is the frequent source of typhus and small-pox.

Texas Fever at Auburn, N. Y.—The Texas fever has atacked the cattle at several slaughter-houses on the outskirts of Auburn, and all beef is sold under certificates of the Board of Health. Street peddling of meat in the city has been stopped for six weeks, and it is probable that all the infected fields will be quarantined until the cold weather. The disease originated in some Texas cattle pastured in the suburbs.

Curious Medical Scraps.—Dr. John C. Peters, of New York, sends us the following curious scraps:

1. Albert Dürer, the great artist, had to endure great griefs, on account of the temper and conduct of his wife Agnes, till he could bear it no longer, and at last was borne down and sunk under them. She now silently did everything to please and comfort him and recompense him for many long years of sorrow, and finally told him in broken sentences that she had, when a little girl, been playing one day in the garden with her little brother Johannes, who had put a small polished stone in his mouth, but finding afterward a beautiful bird's-nest, and holding in his breath for joy, he choked with the stone. His face became red, he sunk down, kicked with his feet, and stared at her with glazed eyes. Agnes ran away in childish fear, and hid herself, without raising any alarm, but her father, on coming home late, and missing the children, went to seek for them, and found Johannes dead in the garden. When they were carrying away little Johannes, Agnes looked sorrowfully from a window in the upper story of the house, and leaning over too far, fell out, striking her head upon the pavement, and now made Albert feel the hollow in her head, which was even perceptible to the eye from a slight depression of the hair. She then began also greatly to complain that she did not hear well when the wind blew from the east. It then came to light by degrees that the wind seemed to her during many fine days and seasons, very often to blow from the east. This was probably a case of pachymeningitis traumatica.

2. The immortal Harvey was a great martyr to the gout, and his method of treating himself was to sit with his legs bare, even if it was frosty weather, on the leads of Cockaine House, where he lived, or to put them in a pail of water till he was almost dead with cold, and then would betake himself to his fire and warm himself. He was also troubled with insomnolency, when he would get up and walk about his chamber in his night-shirt till he was pretty cool, or even until he began to shiver, when he would return to his bed and fall asleep. Finally, on June 3, 1657, he was seized with paralysis, and, as his biographer expresses it, with a dead palsy in his tongue, so that he could not speak. But his intelligence was good, for he distributed presents to his nephews and friends to remember him by. To one he gave the watch which he had used in making his experiments, and to another a different token or gift, and so on, always making signs to one or the other, for he could not speak. This was undoubtedly a case of asphasia.

3. The great Caius, or Kay, or Key, or Dr. John Keyes, died in his sixty-third year, of cancer of the stomach, and before his death was reduced to a state of great bodily weakness, which he attempted to obviate by the use of breast-milk, with funny effects, according to Dr. Mouffet, "for he was peevish and full of frets when he sucked one woman, who was froward of conditions and of bad diet, and contrariwise was amiable, quiet, and well when he nursed from a good and pleasant woman."

4. Linacre died in great agony from the stone, October 20, 1524. He was in the habit of relieving himself with chamomile flowers and parsley roots tied up in a cloth and boiled in water until one-half of the fluid was evaporated. Then the cloth was wrung out and applied hot to the bladder and kidneys, and he drank the warm herb-liquid. In one violent attack the application of the remedy brought away a stone as big as an almond. It is very probable that Bigelow or Keyes would have cured both Linacre and Sydenham, who both died of stone in the blood.

5. Sydenham contended with the gout from the early age of twenty-five, and in his thirty-sixth year was confined to bed with a very violent attack for months, and in 1676 he began to have stone and gravel, of which he died in 1689, aged sixty-five years. When he began to take care of himself and be attentive to his diet, he drank a dish or two of tea early in the morning, and drove to his patients in

his coach till noon, when he returned home and moderately refreshed himself with any sort of meat easy of digestion, and drank somewhat more than one-fourth of a pint of Canary wine, to promote the digestion of food in his stomach, and to drive the gout from his bowels. When he had dined he betook himself to his coach again, and visited his patients, although the symptoms of stone recurred whenever he drove over paved streets, though the horses went very gently; and once having walked much he suffered a very severe paroxysm. A draught of small beer served him for a supper, and he took another draught when he was in bed and about to compose himself to sleep.

THE TOY PISTOL.—A subscriber writes: "Will you or one of your numerous contributors furnish answers to the subjoined questions concerning the now celebrated toy pistol? What is the construction of the toy pistol? How many kinds are found in the market? Which kind is the most harmful? Why is it that so many cases of tetanus are reported in connection with its use? What is the exciting cause of the tetanus? Is the efficient cause chemical or mechanical?"

AN OBSTINATE MALINGERER.—Dr. Thomas F. Houston, of Clarkesville, Ga., sends us the history of a curious case of malingering ending in a very serious surgical operation.

The patient was a colored man accused of stealing a watch. Although he had always appeared perfectly sane, when the day for trial came he was found naked in his cell, refusing to speak, and showing a tendency to fight. Dr. Houston being summoned, pronounced him sane and he was forcibly dressed and carried to court.

During the trial he lay like a dead man on the floor, and in such a condition was carried back to jail. He was tried, found guilty, and sentenced to a year's imprisonment. When he reached the jail after his sentence, he jumped up, struck his heels together, and remarked: "Well, I am guilty, but I would have fooled the law but for that d——— doctor." In one hour he had torn off his clothes and thrown them out of the window, and was acting in the same manner again. "On December 1st," writes Dr. H., "I was requested to see him and decide if he could be removed to the penitentiary. I again examined him, having learned that since the day after the trial he had not spoken or gotten out of his bed, which emitted an intolerable odor from the excretions he had voided in it.

"*Examination.*—Pupils normal, pulse 108, full and hard. Percussion and auscultation found no abnormality. No perceptible tenderness in any portion of the body. Muscles responded normally to electricity. Tongue clean. Found four large blisters, two on each ankle, about 2 inches in diameter, and about 1½ inch high, occupying the site of some old shackle-marks that he had worn during some former service in the penitentiary. The blisters were evidently the effects of two cold nights which had occurred during the time that he was attempting to play the madman, when the thermometer went to about 13° F. The blisters were filled with a dark yellow serum. Such was the rascal's fortitude that the strongest current of a No. 4 galvano-faradic battery would not elicit a wince other than the natural muscular contraction. As the convict had always borne a reputation for intelligence and desperate recklessness, rarely equalled even by his race, I again decided that it was 'pure cussedness,' as they say in the Southwest. But the prison authorities could not induce him by threats or persuasion to show the slightest sign of human intelligence, so they had to let him lie in his filth.

"On the following day the ordinary had him removed to the dwelling of another negro, and left him in his charge. Some days after the negro nurse came to my drug store and bought a bottle of 'Darby's Prophylactic Fluid,' to use in bathing his ankles, stating that they were getting in a bad condition.

"On December 8th I was summoned to see him. On entering the room I remarked to a medical student who accompanied me, 'I smell gangrene.' Upon uncovering his feet a most horrible sight greeted my eyes. He was suffering from gangrene of both extremities, the skin had slipped off like a sock. The toes were wanting, the lower row of metatarsal bones protruded through the flesh fully one-half inch, and in several other places the flesh had fallen off, revealing the tarsal bones. The diseased action extended back as far as the malleoli. Temperature, 103° F.; respiration, 26; pulse, 120, feeling like a cord under the finger. Prescribed elix. beef, iron and wine, egg-nog, and Valentine's meat juice, and a saline antimonial mixture, tablespoonful the first hour, one teaspoonful each subsequent hour until the temperature falls to 99° F., the dose to be increased p. r. n.; the feet to be bathed every hour with a solution of chloride of lime. Gave calomel, grs. v. A line of demarcation finally formed, both legs were amputated, and the patient recovered. He afterward expressed his gratitude for my attention, and admitted that he had been malingering."

NATIONAL MEDICAL EXAMINATIONS.—A surgeon of the Navy sends us the following: "In your issue of March 4, 1882, are seen some remarks upon 'A National Examining Board,' by Navis. These remarks would appear to have been original with the author, while in reality they are merely reflections of previous articles coolly appropriated by Navis. In the *Boston Medical and Surgical Journal* of November 3, 1881, may be seen a very interesting paper by Dr. W. B. Platt, of Baltimore, entitled 'A Plea for United States Medical Examinations,' and in the same journal of December 29, 1881, appears a plan for 'National Medical Examinations,' by Hesperus. Besides the above-mentioned papers, numerous medical periodicals have, from time to time, advocated various plans for the organization of post-graduate examining boards. So the idea, though an excellent one, and worthy of the warmest support, is far from being recent. This scheme of forming general examining boards from the army and navy is the only one that promises the least hope of success, and should it ever bear fruit the originators should receive the country's gratitude."

IPECACUANHA AN OXYTOCIC.—Dr. J. W. Wadsworth, of Saltillo, Mexico, writes: "In THE MEDICAL RECORD of June 3, 1882, appeared an article 'On the Use of Ipecacuanha during Labor,' by Dr. Pitkin, of Newark, N. J., in which the writer calls for the experience of other physicians in its use. In the *New York Medical Journal* for November, 1878, Dr. Pitkin will find a very interesting, original communication from the pen of Dr. Carriger, of Knoxville, Tenn., entitled 'The Use of Ipecacuanha in Labor.' My own experience of its use in labor dates from the publication of that article and prompts me to bear testimony to the truth of

the statement of Dr. Carriger that ipecacuanha 'is both a potent and reliable *uterine motor stimulant*, capable of meeting important indications, in certain cases, much better than any other agent yet brought to our knowledge.' In this country ignorant *parteras* (midwives) mismanage nearly all the labor cases among the middling and poorer classes, after the Chinese plan, the woman kneeling and pulling on ropes attached to a transverse pole, straining until nature exhausts herself, and as a consequence we have many cases of powerless labor, and of retained placenta. Then the physician is sent for, but thanks to Dr. Carriger's observations, these cases do not now annoy me, nor is valuable time lost when two grains of ipecac, taken half hourly, relax the rigid os and bring about a tonic contraction of the uterus far different in its action from that of ergot. I regret having lost my notes taken for the first two years after commencing the use of ipecac in labor, but, nevertheless, constant experience with it has taught me to believe that it not only relaxes the rigid os, but co-ordinating uterine action, actually increases the muscular power of the uterus, proving itself by its physiological action a *true oxytocic*."

A Directory for Nurses has been organized in Philadelphia in connection with the College of Physicians and Surgeons.

Interesting Facts Concerning a Case of Sunstroke.—J. Cresap McCoy, M.D., of Kirwood, Del., communicates the following case:

"On Thursday, June 23d, I was called to see W. R——, colored, aged twenty-three, who, on being questioned, stated that on the day previous he had fallen and injured himself in the left inguinal region. On examination I found a fluctuating tumor three inches in length, quite superficial, and running parallel to Poupart's ligament. By the aid of an exploring needle I found the contents of this tumor to be pus, and a free incision was made to evacuate it. The cavity was washed out with a solution of carbolic acid, one in twenty, and the wound dressed with balsam of peru. A tent made of oakum was left in the wound.

"Nothing unusual happened to the patient that day, he went to work as usual and returned home at night feeling all right. When he arose the next morning he noticed that his head ached a little, and that his *urine, as it passed, caused smarting*. He started for my office, to consult me regarding his condition, about 10 A.M., the morning being an exceedingly warm one. He proceeded about one mile when he grew weak and fell fainting by the roadside. On being conveyed to his home he regained consciousness, and complained of intense headache, and pain in *lumbar region*. When he endeavored to pass water he again noticed smarting, and also that one-half of the volume which he *passed was blood*.

"All his symptoms continued to grow worse, until finally he became delirious, and I was hastily summoned. I found him wildly delirious, eyes bloodshot; temperature (rectal), 106½° F.; pulse, 150; respiration, 40 per minute.

"With the foregoing history, which I obtained from his wife, and with the knowledge of the abscess, I was in a quandary as to whether the case was one of *sunstroke* or *pyæmic abscess of the kidney*. However, from the urgency of the symptoms, something had to be done at once, and reduction of temperature being indicated, I stripped him, threw a thin sheet over his body, and then over this sprayed him by means of a fountain syringe for about two hours, using *tepid* water. I also placed ice bags to his head. In a few minutes from the time that I began the spraying he recovered his consciousness; the temperature (rectal) fell to 104½°, and all his other symptoms abated.

"By the end of the two hours I succeeded in bringing his temperature down to 101°, and the man fell asleep. I left him at this period, but was again summoned during the afternoon, when I found him suffering with a relapse of all his former symptoms, which, however, were not quite as severe as in the first instance.

"I once more applied the ice-bags and used the tepid water spray for about one and one-quarter hour, and he recovered as before, complaining, however, of great pain in back, and inability to pass water. I introduced a catheter and drew off about 6 ʒ of thick, cloudy urine, deeply tinged with blood.

"From this time the patient went on and made a good recovery. He has had no bad symptoms, and feels well generally with the exception of slight smarting accompanying micturition. There was no blood found in urine two days from the time of the attack.

"I think, from the history and course of the case, that there was no doubt but that the diagnosis of sunstroke was the correct one, and the facts which interested me in the case were, the *intense pain felt in the back, and the condition of the urine*.

"I examined the urine by the aid of the microscope, and found blood-corpuscles and large quantities of the urates and uric acid crystals. The deductions which I draw from the case are: 1. That there was of necessity intense engorgement of all the internal organs, and more especially of the liver and kidneys. 2. That this engorgement interfered with the action of the liver and prevented it from acting upon the albuminoids of the portal circulation. 3. The result of this was the formation of urates and uric acid in excess, which passed on to the kidneys for separation from the blood. Here they met with organs similarly congested, and the excess of these salts being so great, they acted as mechanical irritants, and so produced the hemorrhage. The smarting produced by the passage of the urine is explained when the constituents of the urine are taken into consideration."

Nearly a Century and a Half.—The *União Medica*, of Rio de Janeiro, has the following: "In Piedade, District of Votuverava, Francisco Bueno da Rocha lives. He is one hundred and thirty-three years of age and in perfect health. A grandchild of one of his grandchildren is a marriageable woman."

Dr. B. W. Richardson, nothing daunted by the work of resisting the drunkenness of the age, has just been presiding at Exeter Hall, over the foundation of a Society for the Suppression of Juvenile Smoking.

A Quack Doctor, on his death-bed, willed his property to a lunatic asylum, giving as a reason for so doing that he wished his fortune to go to the liberal class who had patronized him.

Internal Administration of Chrysophanic Acid.—The external use of chrysophanic acid is now well known. Its internal use is, however, a novelty, but one which appears to promise good results. At the meeting of the Glasgow Medico-Chirurgical Society on April 7th, Dr. Napier showed two cases of psoriasis which had been treated by the internal ad-

ministration of chrysophanic acid. The initial dose was one-eighth of a grain of the acid rubbed up with sugar of milk, and was gradually increased. The result in both cases was very good, and he believed that this was the first time that this acid had been used in this way. The advantage of this method was, that the remedy might be employed internally where it was too irritating to be applied externally.

BLUE MILK.—The blue appearance which milk sometimes presents after standing a few days is due to an organism which is allied to bacteria, and can be transplanted into other samples of milk and various solutions. It thrives according to the proportion of acid present and the condition of the casein; it appears after a certain degree of acidification has taken place, and prevents the further formation of acid. The casein must also be unchanged; it is then held in solution during the bluing process. The bluing occurs only in presence of oxygen, and is attended with evolution of carbonic acid.

POPLITEAL ANEURISM.—According to *El Progreso* of Cárdenas, Dr. Sims has cured a popliteal aneurism by electro-puncture after three sittings, using the galvano-electric battery of Beltrau.

VOMITING OF URINE.—Generali and Tonini report the case of a patient whom they presented at the Ninth Medical Congress at Genoa. She was thirty-three years of age, and gave a syphilitic history. In October, 1879, she was seized with weakness, headache, epistaxis, and insomnia. The abdomen was retracted. Patient took a light purgative. On November 2d, she was taken with a severe chill, which obliged her to seek her bed. On the following day she was found lying on her back, with pinched features, pulse of 100°, temperature of 33.8° in the axilla. She was suffering from ringing in the ears, severe thirst, and answered questions with difficulty. The tongue was whitish in the centre, and reddish along the edges. Physical examination of the thorax, liver, and spleen revealed nothing. The abdomen was retracted, painful, and sensitive to pressure in the iliac region. The phosphates of the urine were diminished. Inguinal and cervical glands were enlarged. At night the temperature was 39°, pulse 120, and next morning 39.3° and 115 respectively. For three or four days, the temperature varied between 39° and 40°. On the eighth, it rose to 44.4°, while the pulse attained 135. Adynamia was pronounced, the abdomen tympanitic, evacuations frequent, abundant, and fetid. After a temporary amelioration of the symptoms, the patient was again, on the twentieth day, seized with a chill, followed by a febrile movement with a rise of 40°. Acute pain, increased on respiration, was present. The existence of a double pneumonia was diagnosticated. After recovery from this, she was attacked with peritonitis, which left an effusion in the peritoneal cavity, amenable to diuretics. On December 28th, the quantity of urine rapidly diminished to five hundred grammes, and subsequently no urine at all was voided. The patient began to vomit a liquid which presented all the characteristics of urine, containing urea, phosphates, chlorides, alkaline, and earthy sulphates, phosphate and carbonate of magnesia, and pigmentary matter. The microscope revealed gastric and œsophageal epithelium, mucous corpuscles, and the handsome typical crystals of uric acid, resulting from the decomposition of the urate of sodium by the gastric acids. During this vomiting of urine not a drop could be obtained from the bladder. At the end of a month the patient was entirely well. No explanation of the phenomenon is given.—*Cronica Med.-Quir.*

TEETOTALISM A SCIENTIFIC IMPOSSIBILITY.—A correspondent of the *Lancet* writes: "How will the teetotalers reconcile their pledge with the following discovery? M. Muntz, director of the laboratory of the Institut Agronomique, has, by means of an apparatus of his own invention, discovered the presence of alcohol in water. It is true the proportion is almost infinitesimal, yet it is sufficiently appreciable for him to have fixed it at one-hundred-thousandth part and even less. In pushing his experiments further, he discovered the presence of alcohol in all the natural waters—such as those of the rivers and the sea, and even in rain water and melted snow. For instance, in the water of the Seine and in rain-water the proportion of alcohol was about one-thousandth, or one gramme to each cubic metre. The proportion was about the same in the sea-water, but a little greater in cold rain-water; the proportion was also sensibly greater in sewage-water. From the presence of alcohol in rain- and river-water, M. Muntz concludes that it must also exist in the air, and even in the interior of the earth; so that it may be said to exist everywhere in Nature; but he is at a loss to explain its origin. He, however, sets forth the hypothesis that it is produced by the decomposition of organic matter existing on the surface of the globe, in the depths of the sea, and in the different strata of the soil, and after its production, and in obedience of the laws of the tension of vapors, it is diffused in the atmosphere, from which it is eliminated with the meteoric waters.

NATURAL BONE-SETTERS.—I have incidentally mentioned Sugar-Loaf Hill. Almost at its base stands an old house associated with the Sweet family, the "natural bone-setters." Bone-setting has been a specialty with the family for more than a century. They have always been called "natural" bone-setters, but I have heard this tradition touching the manner in which the gift was first acquired and then passed orally from father to son. Dr. William Hunter was one of the most eminent surgeons of his day. He had held a commission as surgeon in the British Army in England, and after his arrival in America he joined the expedition against Crown Point as surgeon. One day a countryman passed his office in Newport, and, on looking in, chanced to see a skeleton hanging in its case. Pausing a moment, he said to the doctor, "There is a defect in your anatomical preparation." The doctor, on looking up, and seeing an uncouth-looking fellow at the door, smiled as he asked, "Wherein is it wanting?" "Oh, you may laugh," said the countryman, "but one of the bones in that hand is out of place." The doctor looked and said: "You are right; now tell me how it is that you know anything of anatomy." "Some day, doctor, you will be called to Narragansett; when there, stop at the door of Job Sweet, and I'll show you." Not long after the doctor was called to Point Judith, and before he returned, he called on Sweet, who placed before him a large folio volume of anatomical plates, engraved in a superb manner. The doctor looked at the volume with surprise as he said, "Where did you get it?" "Some years ago," said the bone-setter, "a vessel went to pieces on Point Judith. Many persons visited the scene of the wreck, I among the number, and there I picked

up this volume, which had floated ashore. I could not read it (it was in French), but became absorbed in the prints, made them a study, put the information so acquired to practice as opportunity offered, and, if I do not understand the text, I think I know all about the plates." This incident was related to me by a descendant of Dr. Hunter, who had it from his ancestors. — *Cor.* (*Narragansett Pier*) *Evening Post.*

Women in Sanitary Work.—A number of ladies who are prominent in professional and philanthropic work have organized a "Woman's Sanitary Association," designed to be national in its purposes and scope. It proposes to agitate and promote measures of practical sanitary reform. At their first meeting, at Dryden Springs, N. Y., August 29th, Miss S. S. Nivison, M.D., was elected President. Mrs. C. M. Clark delivered a lecture on the "Economic Sanitary Arrangements of Paris and its Hospitals."

Appearance of the Plague.—The Siberian plague is appearing to an alarming extent in most widely separated quarters of European Russia. One death from the disease has occurred at Odessa.

The Cholera Abroad.—A cable dispatch from Yokohama, received August 29th, states that out of 775 cases of cholera within twenty days at Yokohama 572 cases proved fatal. At Tokio about 80 cases and 50 deaths occur daily. An official dispatch from Manila, Philippine Islands, states that 300 deaths from cholera occurred there on August 25th. Two hundred and ninety-four of the victims were natives.

"Horse Sense" in Diagnosis.—We commend the following item to such as are often unable to make a diagnosis in apparently obscure cases:

About two miles from town he suddenly checked his horse, gazed intently on the ground, and said: "Some fellow has lost his saddle-horse here this morning."

There was no advertisement on any of the trees offering a reward for a lost horse, and as there was no lost horse in sight, we were at a loss to understand how, if a horse was lost, our friend could know so much about it.

The doctor inquired: "How do you know that a horse has been lost?"

"I see his tracks."

"Are there not hundreds of horses pasturing on the prairie, and how do you know that this is not the track of one of them?"

"Because he is shod, and the horses herding on the prairies do not wear shoes."

"How do you know that he is a saddle-horse, and lost?"

"I see a rope track alongside his trail; the horse has a saddle on, and the rope hangs from the horn of the saddle."

"But why may he not be a horse that some one has ridden over this way this morning, and why do you insist that it is lost?"

"Because, if a man had been on his back he would have ridden him on a straight course, but this horse has moved from side to side of the road, as he strolled along, and that is a plain sign that he grazed as he went, and that he had no rider."

"After that it would not surprise me," said the doctor, "if you were to tell us the age of the horse and the name of the owner."

"Well, that would not be very hard to do. There are signs that have told me the owner's name, and there are other signs that, if I had time to examine, would tell me his age. I know he is one of old man Pendergrast's horses. Pendergrast has a large bunch of horses down in the bottom, and an old nigger down there does all his shoeing, and shoes no other horses except his. So we know his shoe track just the same as we know his brand."

After this conviction on circumstantial evidence, it would not have seemed extraordinary if the Remnant had given us his opinion of the life and character of our great-grandmothers, drawing his conclusions from an examination of some of our physical peculiarities.

It is wonderful how expert these men become in reading what they call "signs" on the prairie or in the woods. No sign escapes their practised eye; all manner of tracks, trails, and marks are to them data on which to base conclusions. The peculiar movement of an animal will indicate the presence of some other animal in the neighborhood. A broken limb of a tree, a crushed weed, the débris around a camp fire, the flight of a buzzard, and other such signs, are to the cow-boy and the frontiersman what the signboards and advertisements are to the people who live in cities.—*Texas Siftings.*

The Sanitary Institute of Great Britain holds its annual meeting at Newcastle-on-Tyne, September 26th. Dr. Denis Embleton presides over the Sanitary Section.

Death of the Discoverer of the Present Theory of Blood Coagulation.—Dr. Andrew Buchanan, late Professor of Physiology in the University of Glasgow, died July 9th, at the age of eighty-four. His view of the cause of the coagulation of the blood, sustained by many experiments, was very nearly like the present accepted one, which is credited to A. Schmidt. Dr. Buchanan was also inventor of the rectangular staff for lithotomy.

Death of Professor Balfour.—Universal regret will be experienced at the announcement that Mr. F. M. Balfour, the recently elected Professor of Morphology at Cambridge, met his death quite recently through falling over a precipice in Switzerland. Francis Maitland Balfour had made for himself a position among English men of science which was inferior to that of no one in the whole field of biology. As a comparative anatomist he was famous throughout the world, and his magnificent work on Embryology is already a standard and classical treatise on the subject. The University of Cambridge sustains an irreparable loss by the sad mishap by which one of its brightest ornaments is removed from the ranks of the Royal Society. The mode by which Professor Balfour came to his end, too, will add to the sorrow that his decease will everywhere evoke.

Seventeen Anti-Vaccinators have been summoned at Eastbourne, England, for refusing to obey the order of the local justices to have their children vaccinated. A fine of £1 and costs in each case was inflicted.

A New Journal devoted especially to neurology is announced to appear soon. It will be published at Naples bi-monthly, and will be edited by Professor Francesco Vizioli of that city.

A Whole Family has been accidentally poisoned at Sallède, near Vic-le-Comte, in the Department of Puy-de-Dôme, by flour containing a lead salt.

Original Communications.

ON THE CONVALLARIA MAIALIS.

A New Remedy for Heart Disease.

By E. P. HURD, M.D.,
NEWBURYPORT, MASS.

This plant, commonly known as "lily of the valley," is a native of this country, being a garden flower of singular beauty and fragrance, also growing wild in almost all parts of the United States. Not much medicinal virtue has been attributed to it, although from time immemorial the peasants of Western Europe, where also it is native, have regarded it as a certain remedy for dropsy. In 1880, two Russian doctors, Troitzky and Bojojawlensky, published in the *Wratsch* the results of several interesting experiments with the convallaria in heart affections attended with dropsy, and the statements of the Russian doctors were confirmed by Professor Botkin, of St. Petersburg.

Professor Germain Sée, of Hotel Dieu, Paris, has recently been experimenting with the convallaria maialis, first on animals to determine its physiological and toxic properties; and then on man, selecting for his subjects patients in the hospital suffering from well-marked forms of heart disease. The results of his experiments and observations are published in the *Bulletin General de Thèrapeutique* for July 30, 1882.

The subject is so interesting and so important that I have reproduced portions of Professor Sée's article. In common with other physicians, I have long felt the need of some reliable substitute for digitalis in affections of the heart characterized by enfeeblement of the circulation and asystolism. We ring the changes on the preparations of digitalis till we cease to see any good result from the medicament; we resort to "cactus," "coca," "caffeine," and "cereus bonplandii," without success. If the "lily of the valley" will give us any help where digitalis fails, we shall joyfully welcome the new remedy.

1. *Active principle.*—The active principle is an amorphous bitter glucoside called convallaramin, obtained by treating the aqueous extract of the flowers by alcohol and chloroform. Convallaramin is comparable to digitaline in activity, though differing in effects from digitaline.

2. *Preparations.*—The best preparations are the extracts which are thus classed by Professor Sée in their order of merit: (1) The aqueous extract of the leaves. This is rather more reliable though less strong than (2) the aqueous extract of the flowers. (3) The extract of the whole plant, root, leaves, and flowers. The watery infusion of the leaves or flowers is a good form in which to prescribe the convallaria for cardiac patients.

3. *Experiments on animals.*—A drop of the extract of the flowers brought in contact with the naked heart of the frog arrests the action of that organ in about two minutes. The same result is obtained when the medicament is introduced under the skin. The convallaria is then a poison which, like digitalis, upas antiar, erythrophleum, arrests the heart in systole. In the case of the dog, four drops of the extract injected into a vein, causes death in ten minutes by arrest of the heart. The heart is first slowed and the respirations quickened, then the heart's action becomes irregular and the pulsations become faint and very rapid; the blood-pressure first augments and then is lowered, the respirations become slower and slower; the heart's action ceases, pressure falling to zero, and the respiratory movements cease in their turn. The excito-motor power of the nerves and nerve-centres is unaffected. The excitability of the pneumogastrics is weakened, not destroyed. No diuretic effects were observed in the dog.

4. *Clinical observations.*—Professor Sée reports twenty cases, occurring in hospital and city practice, in which the effects of the convallaria were noted. Five were cases of mitral insufficiency, characterized by want of rhythm ("arythmie"), œdema of the limbs, dyspnœa, inability to ascend stairs, asystolism more or less pronounced. The extract of convallaria maialis was given in doses of one-half gramme (in some cases increased to one gramme) daily, and to these five patients, with marked benefit. The heart's action became stronger and more regular, the breathing became better, there was a notable increase in the urine, and the condition generally of the patient was improved. In all these cases the œdema of the limbs disappeared under the use of the medicine The sixth case was one of mitral constriction which was immediately benefited. There was a speedy improvement in the pulse, with increase of urine and decrease, finally disappearance, of the œdema. Two cases of "primitive dilatation of the heart" were treated successfully with half gramme doses daily, of the extract. Several cases of aortic insufficiency were relieved of the more distressing symptoms by the same remedy. In three cases only of the twenty was the medicine given without success. One was complicated with lead poisoning, another was too far advanced for any remedy to take effect, the third was a case of atheromatous disease of the heart, aorta, and arteries, with interstitial nephritis; there was in this patient an amelioration for a few days, but the amelioration was not persistent.

CONCLUSIONS.

Dr. Sée's conclusions are as follows:

First.—The convallaria maialis constitutes one of the most important cardiac remedies which we possess.

Second.—In the form of the aqueous extract of the entire plant (which is a very convenient way of giving the medicine), administered in the dose of from one-half gramme to one and one-half grammes daily, the convallaria produces on the heart, blood-vessels, and respiratory organs effects constant and constantly favorable; to wit, slowing of the beatings of the heart, with often a restoration of the normal rhythm, and on the other hand, augmentation of the energy of the heart, also of the arterial pressure; in fine the inspiratory force is increased, and the *besoin de respirer* is less injurious, less painful.

Third.—The effect the most powerful, the most constant, and the most useful is the abundant diuresis, which is above all things essential in the treatment of cardiac dropsies.

Fourth.—The therapeutic indications are summed up as follows:

(a.) In palpitations resulting from a state of exhaustion of the pneumogastric nerves (cardiac paresia), the most frequent source of palpitations.

(b.) In simple cardiac arythmia, with or without hypertrophy of the heart, with or without lesions of the orifices or valves of the heart.

(c.) In mitral constriction, especially when it is accompanied with failure of compensation on the part of the left auricle and right ventricle; the contractile force augments visibly under the convallaria, as the sphygmograph testifies.

(d.) In mitral insufficiency, especially when there are pulmonary congestions, and when, as a consequence, there is dyspnœa with or without nervous trouble of the respiration.

(e.) In Corrigan's disease the peripheral arterial pulsations disappear, and respiration becomes markedly restored. In dilatation of the left ventricle without compensatory hypertrophy it restores energy to the heart, which tends to become more and more feeble and dilated.

(f.) In dilatations of the heart with or without hypertrophy, with or without fatty degeneration, with or without sclerosis of the muscular tissue, the indications of the convallaria maialis are clear.

(g.) In all cardiac affections indifferently, from the moment that watery infiltrations appear, the convallaria has an action evident, prompt, and certain.

(h.) In lesions with dyspnœa the effect is less marked. To combat cardiac dyspnœa, convallaria is inferior to morphia and especially to iodine, but morphia suppresses the urine, and the preparations of iodine are every way preferable. The combination of convallaria maialis with iodide of potassium in the treatment of cardiac asthma constitutes one of the most useful methods of treatment. Finally, in cardiopathies with dropsy the convallaria surpasses all other remedies. One is often obliged to suspend the employment of digitalis on account of vomiting, digestive disturbances, cerebral excitation, the dilatation of the pupil which it so often produces after a prolonged use of this medicament, etc.

The final action of digitalis is exhaustion of the heart, increase with enfeeblement of the heart's pulsations—just the opposite effects from what we seek when we give the drug.

Convallaria maialis has no deleterious effects on the economy, and has no cumulative action.

Postscript.—I have recently obtained a liquid extract of the Lily of the Valley from the manufactory of Parke, Davis & Co. These enterprising pharmacists have advertised the cardio-tonic virtues of convallaria in terms almost identical with those employed by the distinguished French professor. It is gratifying to observe that their claim for convallaria, "that it is a safe and efficient substitute for digitalis," has received such high endorsement, and from a medical writer and teacher evidently ignorant of the fact that certain eclectic practitioners in this country have for years prescribed the lily of the valley in cardiac dropsy.

I have lately employed Parke, Davis & Co.'s preparation in two cases. The one is a patient suffering from Corrigan's disease—partly compensated. He is incapacitated for any but very moderate exercise; has attacks of syncope, dyspnœa, and angina. Though he has taken the convallaria only three days, he has been entirely free from his usual faint and giddy turns, has had no angina pectoris, and has been able to do his work with increased comfort. The other is a case of aortic and mitral insufficiency, with enormous dilatation and marked asystolism. There is dyspnœa (orthopnœa) from pulmonary stasis and hydrothorax, some œdema of the extremities, vomiting and digestive disturbance. This patient is greatly dependent on hypodermics of morphia. I have prescribed the liquid extract of convallaria in doses of five drops every four hours. So far the effect has been gratifying. There is more force in the cardiac pulsations, and in the pulse at the wrist. The dyspnœa is relieved. The quantity of urine is notably augmented. The patient has better nights and can take more food. I do not look for any permanency in these good results; granulo-fatty degeneration of the heart is evidently far advanced.

August 30th.—Mrs. C——, the patient referred to in the last paragraph, continues to improve after a fortnight's use of the new remedy. The cardiac contractions are slower and more friable, the dyspnœa has disappeared with the pulmonary stasis and the hydrothorax. She can now lie down *flat on her back.* This relief has been coincident with a copious diuresis, commencing the third day of the administration of the medicine. For several days the quantity of urine passed during twenty-four hours has been as high as sixty ounces (before commencing the remedy the average quantity *per diem* was eight ounces). The dose now taken of the convallaria maialis is twelve drops every four hours. For a while I was able to suspend the morphine injection (one grain at night subcutaneously), but latterly I have been obliged to resume it on account of the return of the angina, from which she has long been a sufferer. It is evident that the convallaria has done all that any remedy could be expected to do in this case, as atheromatous changes in the nutrient vessels of the heart are more than probable.

ON NERVE-STRETCHING.

By W. J. CHANDLER, M.D.,
SOUTH ORANGE, N. J.

Part II.

Let us now, in conclusion, consider the opinions of the medical profession in regard to nerve-stretching.

We here notice not only a diversity of views, but also a tendency to mould the public opinion in almost *point-blank opposition to statistical facts.*

From many personal communications we make a few extracts.

"April 13, 1882.

"My experience in nerve-stretching has been quite limited, and, as far as it goes, leads me to believe that no permanent benefit results from the practice. A temporary respite is undoubtedly secured, but only temporary. "D. Hayes Agnew."

"April 18, 1882.

"There is no question as to the value of nerve-stretching. This is, practically, what is done when we relieve a spasm of the muscle of the leg by stretching the limb. . . . . The only question is, whether the danger attending the exposure of large nerves by incisions and then making extension to a degree beyond what is normal, is not greater than the possible or probable advantages will warrant. . . . . I have never exposed a nerve for the purpose of stretching it, and shall not until the weight of testimony in its favor is greater than it is at present. "Frank H. Hamilton."

Dr. Wm. A. Hammond thinks: "Much is to be expected of nerve-stretching in the neuralgic affections. In locomotor ataxia it will only produce temporary relief."

Dr. Geo. M. Beard writes, April 13, 1882: "Nerve-stretching is an addition to our means of treating nervous disease, but not as important as was at one time hoped it would be. The disappointments following it have been many and are increasing. It is especially indicated in neuralgia and local chorea. In ataxia it is quite uncertain, and many of the good effects have been of a temporary character; but it is justifiable."

Dr. A. C. Post writes, April 13, 1882: "It appears to be especially applicable to the treatment of neuralgia and spasmodic affections. I intend to try it when appropriate cases shall present themselves."

The above extracts may be taken as a fair representation of the professional opinion in this country.

It may be styled a *generous conservatism*, and we respect it.

At a recent discussion in the Berlin Medical Society, Prof. Langenbeck read a paper containing deductions from one hundred cases operated on by himself at St. Lazonus Hospital. Eighty-four per cent. of the neuralgic cases were cured. They were observed from three to eighteen months after the operation. In his general conclusions, he observes, that while we have much to learn as to important details—such as the amount of traction, direction of traction, what diseases and in what stage of disease the operation is most effective, etc.—we must admit that in nerve-stretching we have a most valuable weapon with which to combat various painful affections. The discussion which followed has become a part of the medical literature of the world, and the general impression produced is that the operation is a failure.

We could not close this paper without noticing such a discussion, the more especially as it finds an echo of endorsement in this country.

Dr. D. W. Yandell sends us the following from the Louisville *Medical News*, as expressing his views on the subject.

"At a society meeting in this city, a few days ago, it seemed to be the general opinion that while nerve-stretching as a remedy for centric diseases had failed to come up to expectation, it was still worthy of trial in the treatment of peripheral affections—such as neuralgias and local spasms.

"Our latest advices are calculated to destroy all faith in it as a remedial measure. In the *Medical Press and Circular* for April 12th is a summary of a debate on this subject, in which the leading Berlin surgeons and physicians took part. We learn from it that Dr. Westphal stated that since 1877, when he first undertook this operation, he *had not seen a single case which it had helped.*[1] On the contrary, a detailed account was given of cases of tabes dorsalis, tabes dorsalis spastica, paralysis agitans, and neuralgias of all kinds made worse by stretching the nerves. He related a case which illustrates the extraordinary pertinacity with which the experiment was tried, only to fail in the end. Dr. Lagenbeck had within six months operated seven times on one patient. He stretched both crural nerves and both sciatics; then he cut a piece out of the peroneal, another out of the plantar nerve, and, finally, as the great toe was the chief seat of pain he amputated that; and, notwithstanding all this, the patient's condition was not improved in the slightest degree. He had seen the case of Nussbaum's celebrated as a successful stretching of an intercostal nerve. The patient assured him (Westphal), shortly after the operation, that the pain was as bad as ever; in fact, it seemed even worse than before. At any rate, the result was far from being as successful as was generally believed.

"Doctors and patients alike are enamored of novelty, and both feel a psychical impression that monopolizes attention when some startling operation in which great confidence is expressed has been performed.[2] Westphal attributes the temporary improvement sometimes seen to this psychological effect, which on ataxic cases, naturally hopeful, is especially marked. A sanguine doctor infuses faith and hope into the patient's mind; and, as a result, for a time he appears to be benefited by anything new or wonderful, whether it be the galvanism of Remak, or this more formidable measure of cutting down upon and pulling the offending nerve.

"Dr. Bardeleben testified to the accuracy of Westphal's report of the sequel to operation in Nussbaum's case. He stated that though he had performed nerve-stretching for the medical staff very frequently, he had never seen good results.

"We give great prominence to these conclusions, in the hope that American surgeons, who have just fairly welcomed this procedure, will see the propriety of bidding adieu to it. The chances of benefit from it are not great enough to justify the pain and risk attending its performance."

When men rely upon ridicule and misrepresentation, they but confess the weakness of their cause. While we may not commend the wisdom of seven operations on one patient, they attest a *firmness of conviction* as the outgrowth of *successful experience* which even ridicule cannot overcome. But when we are told that Nussbaum's "intercostal" case is extolled as a "success," we are grossly misled. For a short time it was hoped and believed that a cure had resulted, but the contrary proved to be the truth; and this case has been recorded in the list of failures in all the reports which we have examined.

Again, Dr. Westphal asserts that he has not seen a single case benefited by the operation. This statement is astounding; for we must believe either that the learned gentleman's experience has been singularly unfortunate, or else that there are others than "ataxic persons" who are "only too ready to believe whatever is required of them."

In either case, it proves nothing. Five failures will not disprove even one success; and when statistics gathered from all parts of the world by careful, trusty observers testify so frequently and conclusively in favor of the operation, we must either admit this favorable testimony, or impugn the wisdom, competence, and integrity of some of the most highly esteemed and conservative operators of the present day.

It is not the first time that statistics and public opinion have come in conflict. In 1809, Dr. McDowell, of Kentucky, published thirteen cases of ovariotomy, eight of which were successful. And yet as late as 1850, a medical society in London considered it "derogatory to the medical profession to even discuss ovariotomy."

Tracheotomy has met with an equal and perhaps more just opposition.

Paracentesis of the chest was considered so hazardous a procedure that the illustrious Dupuytren, when offered its relief in his own case, replied that he would rather "die by God's hand than by man's." And thus has it been with the majority of operations which to-day have the confidence of the profession. Why, then, should we expect any less opposition in the novel operation of nerve-stretching.

No! it will be opposed; it will even be misrepresented. But, while it may not accomplish all that its most ardent advocates claim for it, while, too, there is much to be learned as to particular modifications of the operation, and their adaptability to different forms of disease, we feel confident that an operation which develops so much statistical strength, has certainly enough of real merit to overcome opposition, and stand, in the future, side by side with ovariotomy, tracheotomy, and paracentesis thoracis, in the honored list of accredited surgical operations.

[1] A letter from Professor Westphal, received since this paper was written, leads me to infer that he would restrict his unfavorable criticisms to cases of tabes dorsalis.

[2] Dr. Westphal "believes the so-called results are the effect, psychologically, upon the patient undergoing a great operation, which he is assured must prove successful in his case; and from the sanguine view which ataxic patients take of their condition, they are only too ready to believe themselves better if required."

TABLE A.

7	Blum 5	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
8	Blum	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
9	Berger 6	.....	Sciatica.	.....	.....	.....	Cured.	
10	Büttner	m. 36	Sciatica.	8 years.	Dec. 13, 1881.	Right sciatic.	Cured.	For history, see Appendix.
11	Büttner	m. 40	Sciatica.	8 months.	June 17, 1881.	Right sciatic.	Cured.	For history, see Appendix.
12	Bramwell 7	m.	Sciatica.	.....	.....	.....	Cured.	First operation a failure. Second operation successful.
13	Bramwell	m. 27	Sciatica.	.....	.....	.....	Improved.	Second operation successful.
14	Bramwell	m. 46	Sciatica.	14 months	.....	.....	Cured.	Followed by temporary paralysis and anæsthesia.
15	Bramwell	f. 28	Sciatica.	.....	.....	.....	Cured.	Two operations, at intervals of 1 year.
16	Bramwell	m.	Sciatica.	.....	.....	.....	Improved.	
17	W. A. Boyd 8	m. 56	Sciatica.	7 months.	May 27, 1878.	Right sciatic.	Cure.	Anæsthesia for six weeks after stretching, after which cure was complete.
18	Cameron 9	m. 39	Sciatica.	7 months.	.....	.....	Cure.	Two stretchings.
19	Cheyne..... 2	m 41.	Sciatica.	10 months	April 23, 1877.	Sciatic.	Cure.	Fatty degeneration of nerve.
20	Cheyne..... 10	m. 40	Sciatica.	5 years.	April 19, 1877.	Sciatic.	Cure.	
21	Cheyne	m. 40	Sciatica.	.....	.....	.....	Cure.	
22	Davidson.....11	m. 62	Sciatica.	5 years.	Sept. 18, 1881.	Right sciatic.	Cure.	Contracture of limb relieved by the stretching. Quite forcible extension.
23	Davidson.....	m. 35	Sciatica.	1½ year.	Oct. 27, 1881.	Right sciatic.	Cure.	Less forcible extension. Slight return of pain after three weeks, which, however, soon disappeared permanently.
24	Davidson.....	m. 65	Sciatica.	4 years.	Nov. 18, 1881.	.....	Cure.	Atrophy of limb and shortening overcome by stretching.
25	Davidson.....	m. 31	Sciatica.	8 years.	Dec. 9, 1881.	Right sciatic.	Great improvement.	Considerable shortening; slight atrophy. Very much relieved by stretching.
26	Dougherty.....	m. 43	Sciatica.	4 months.	Dec. 31, 1881.	Sciatic.	Temporarily improved.	See Appendix.
27	Esmarch 12	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
28	Fenger 3	f. 35	Sciatica.	1 year.	Oct. 6, 1880.	Right sciatic.	Cured.	Nerve exposed in upper third. Suppuration for eight weeks. Temporary paralysis of sphincter ani and anal region and thigh.
29	Fenger	f. 45	Sciatica from cancer of the pelvic bones.	4 months.	Jan. 6, 1881.	Left sciatic.	Relief.	Pain ceased after operation. Death from exhaustion, thirty-six days later.
30	Fenger	m. 60	Sciatica, due to obscure central disease.	.....	Aug. 7, 1880.	Left sciatic.	Relief.	Pain ceased after operation. Death from central disease four weeks later.
31	Gillette.....13	f.	Sciatica.	16 months	.....	.....	Cured.	
2	Gillette.....	f. 43	Sciatica.	.....	.....	.....	Cured.	
3	W. A. Hammond..	m.	Sciatica.	Several	.....	Sciatic.	Cured.	These four cases had atrophy of affected limb. The sciatic was exposed in the lower third, and only moderate traction made.
4	W. A. Hammond..	m.	Sciatica.	years.	.....	Sciatic.	Cured.	
35	W. A. Hammond..	f.	Sciatica.	Several	.....	Sciatic.	Cured.	
36	W. A. Hammond..	f.	Sciatica.	years.	.....	Sciatic.	Cured.	
37	Hildebrand 14	f. 32	Sciatica.	.....	.....	Left sciatic.	Cured.	Nerve exposed in popliteal space. Woman able to work in eight days.
38	Küster 15	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
39	Küster 16	.....	Traumatic sciatica.	.....	.....	Sciatic.	Cured.	Two operations.
40 to 47	Langenbeck 15	.....	Sciatica.	.....	.....	Sciatic.	Cured.	Nerve exposed in lower third. Cases under observation from three to eighteen months.
	Langenbeck 15	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
48	Maag.....17	f. 20	Sciatica.	18 months	.....	Sciatic.	Cured.	
49	Maag.....	f. 19	Sciatica.	3 months	.....	Sciatic.	Cured.	Wound suppurated.
50	Macfarlane.....18	f. 29	Sciatica.	11 months	.....	.....	Cured.	
51	Macfarlane.....	.....	Sciatica.	10 months	Nov. 3, 1877.	Sciatic.	Cured.	
52	Manle.....19	m. 45	Sciatica.	9 months	.....	.....	Cured.	
53	Massing..... 3	10	Traumatic sciatica.	.....	.....	Sciatic.	Improved.	Contracture, with hyperæsthesia. No improvement until seven weeks after operation. Seven months later he was better, though still unable to walk.
54	Massing.....20	12	Traumatic sciatica.	.....	.....	.....	Improved.	
55	Mackintosh.....21	m. 41	Sciatica.	14 years.	.....	.....	Cured.	
56	Morton.....22	m. 33	Sciatica.	8 months.	Oct. 22, 1881.	Left sciatic.	Cured.	
57	Naismith.....23	m. 54	Sciatica.	7 years.	Aug. 10, 1880.	Left sciatic.	Cured.	
58	Nussbaum.....24	.....	Sciatica.	.....	.....	Left sciatic.	Cured.	Nerve exposed in popliteal space. Hemorrhage from popliteal artery.
59	Panas	m.	Traumatic sciatica.	4 years.	.....	Left sciatic.	Cured.	
60	Patrubau.....26	m.	Sciatica.	3 years.	.....	.....	Cured.	
61	Patrubau..... 3	.....	Sciatica.	.....	.....	Sciatic.	Improved.	
62	Pierson.....	m. 39	Sciatica.	Several years.	June 30, 1881.	Sciatic.	Cure.	See Appendix.
63	Pooley 27	m. 30	Sciatica.	9 years.	May 12, 1880.	Right Sciatic.	Cure.	
64	Purdie 28	m.	Sciatica.	Several months.	.....	Sciatic.	Cure.	No suppuration.

(1) *Sciatica.—Continued.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
65	Walter Pye.....29	.....	Sciatica.	.....	.....	.....	Improved.	
66	Richardson. ...30	.....	Sciatica.	.....	.....	Sciatic.	Cured.	
67	Spencer 31	m.	Sciatica.	7 months.	Sept. 3, 1879.	Sciatic.	Cured.	
68	Trendelenburg..32	.....	Sciatica.	.....	.....	Sciatic.	Partial relief	Sciatica due to spinal injury.
69	Trombetta.....33	m. 75.	Sciatica.	.....	.....	.....	Cured.	
70	Hahn.....	f.	Sciatica, with epileptiform convulsions.	.....	.....	.....	Improved.	A previous excision had failed. The improvement has continued for over six months.

(2) *Traumatic Neuralgia.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Andrews..... 3	m.	Tonic spasm, with pain in both legs.	1 year.	May 15 and 24, 1876.	Both crural and sciatics.	Cured.	Stretching *left* crural and sciatic relieved *right* limb. Stretching right crural and sciatic relieved left limb. Seven months after operation, patient performed the duties of a sailor.
2	Ashhurst.....34	m. 33.	Neuralgia, hand and arm.	10 months	.....	Medium ulnar and musculo spiral.	Improved.	
3	Ashhurst	.....	Traumatic neuralgia.	.....	.....	Musculo spiral.	Temporarily improved.	
4	Ashhurst	.....	Traumatic neuralgia.	.....	.....	Medium.	Cured.	Recovery remained complete one year after stretching.
5	G. Byrd.....35	m. 21.	Neuralgia after amputation.	.....	.....	.....	Failed.	
6	Callender.....36	m. 20.	Neuralgia after amputation.	1 year.	.....	Medium.	Cured.	The right hand was injured by a circular saw. Amputation; neuralgia of stump and arm.
7	Callender.....37	m.	Neuralgia after injury.	.....	.....	Medium and ulnar.	.....	
8	Czerny 38	m. 24.	Neuralgia of parts supplied by ulnar nerve.	.....	.....	Ulnar.	Improved.	Neuralgia due to suppuration in elbow-joint. Ulnar stretched in axillary plexus. Recovery not perfect.
9	Crede 39	.....	Neuralgia of parts supplied by left radial.	18 months	.....	Brachial plexus.	Cured.	
10	Duplay.....40	m. 26.	.....	.....	.....	.....	Cured.	Neuralgia due to compression of the ulnar nerve.
11	Estländer 41	m. 27.	Traumatic neuralgia, right hand.	.....	.....	Medium.	Improved.	
12	G. M. Hammond 42	m. 45.	Traumatic neuralgia, right hand and arm.	6 months.	May 29, 1881.	Right ulnar.	Cured.	No return of pain one year after the operation.
13	Hoover.....27	.....	Traumatic neuralgia, left leg.	Many years.	May 25, 1880.	Left sciatic.	Relieved.	Accompanied by spasms of muscles of leg.
14	Küster 15	m.	Traumatic neuralgia.	.....	.....	Ulnar.	Temporary relief.	
15	Peterson 43	.....	Traumatic neuralgia.	.....	.....	Post tibial.	Cured.	Wound of left leg. Long-continued, deep-seated pain. Extravasated blood found in sheath of nerve.

(3) *Neuralgia of Different Branches of Fifth Pair of Cranial Nerves.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of operation.	Nerve Stretched.	Result.	Remarks.
1	Croft..... 3	.....	Facial neuralgia.	.....	....	Infra orbital.	Cured.	Spasms of face; ⅝ inch of nerve excised; nerve then stretched. Two light attacks during first year after operation; after that, recovery was complete.
2	Czerny 38	m. 60.	Neuralgia of ophthalmic branch.	.....	.....	Frontal.	Failed.	
3	Czerny	m. 63.	Supra orbital neuralgia	.....	.....	Frontal and supra orbital	Relieved.	Stretching was followed by excision, to complete the cure.
4 to 12	Hahn 44	.....	Neuralgia of 5th pair.	.....	.....	.....	Temporarily improved.	All cases relapsed after six to eight months.
	Hahn 44	.....	Neuralgia of 5th pair.					
13	Hahn 45	.....	Neuralgia inf. max.	.....	.....	.....	1 improved.	Nerve was stretched and resected.
14	Hahn 45	.....	Neuralgia inf. max.	.....	.....	.....	1 failed.	Nerve was stretched and resected.
15	Hahn	.....	Supra and infra orbital neuralgia.	.....	.....	.....	Failed.	
16	Higgins 29	m. 62.	Neuralgia of ophthalmic branch.	3 years.	.....	Supra orbital.	Cure.	Neuralgia followed extirpation of the left eye.
17	Higgins	m. 53.	Neuralgia of ophthalmic branch.	1 year.	.....	Right supra orbital.	Cure.	Neuralgia followed extirpation of the right eye.
18	Kocher.....46	m. 32.	Supra orbital neuralgia	14 years.	.....	.....	Cured.	

(3) *Neuralgia of Different Branches of Fifth Pair of Cranial Nerves.--Continued.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
19	Küster 15	.....	Neuralgia of 5th pair.	.....	....	.....	1 cured.	
20	Küster 15	.....	Neuralgia of 5th pair.	.....	....	.....	1 unknown.	
21	Lange	m. 63	Neuralgia of 5th pair.	.....	.....	Infra orbital.	Cured.	Nerve twice resected, and failed to relieve. Stretching has given relief up to the present time (four months).
22	Langenbeck 47	.....	Neuralgia of 5th pair.	.....	.....	Buccal branch of inf. max.	.....	
23	Massing 48	f. 60	Facial neuralgia.	Many yrs.	.....	Sup. orbital.	Cured.	
24	Massing 49	.....	Ophthalmic neuralgia.	.....	.....	Sup. orbital.	Cured.	
25	Nussbaum 3	.....	Neuralgia of supra and infra orbital.	.....	.....	R. and L. supra and infra orbitals.	Temporary relief.	Stretched and excised. Relapse on left side after a few weeks.
26	Polilaion 50	m. 62	Spasmodic facial neuralgia.	3 months.	.....	Inf. dental.	Cured.	
27	Polaillon 51	m.	Neuralgia of 5th pair.	.....	.....	Sup. dental.	Cured.	
28	Purdie 28	.....	Epileptiform neuralgia 2d fr. of 5th.	.....	.....	Infra orbital.	Cured.	
29	Quinquand 52	f. 70	Spasmodic facial neuralgia.	16 years.	.....	Ext. frontal.	Failed.	
30	Quinquand	f. 76	Supra orbital neuralgia	6 months.	.....	Ext. frontal.	Cured.	
31	Spence 31	m.	Spasmodic facial neuralgia.	2½ years.	May 22, 1879.	Infra orbital.	Cured.	On fifth day after operation, the pain returned. The wound was opened and the nerve stretched again, after which, relief was permanent.
32	G. Stewart 29	m. 70	Neuralgia sup. max.	16 years.	.....	.....	Cured.	Two stretchings.
33	Vogt 53	f. 50	Spasmodic facial neuralgia.	6 years.	.....	Infra orbital.	Cured.	
34	Vogt	f.	Neuralgia lower jaw.	10 years.	.....	Inf. dental.	Cured.	
35	Walsham 35	f. 50	Spasmodic facial neuralgia.	10 years.	.....	Infra orbital.	Cured.	
36	Crede 47	f.	Facial neuralgia.	9 years.	.....	Inf. maxill'y.	Cured.	Stretched and excised.
37	Baillou 98	.....	.....	.....	.....	Inf. dental.	Great improvement.	Baillou trephined the inf. maxilla and stretched the nerve 1¼ centimetre. The nerve was not diseased.

(4) *Miscellaneous Neuralgic Affections.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	D. Hayes Agnew 54	.....	Neuralgia.	.....	.....	Sciatic.	Temp. relief.	Neuroma removed.
2	D. Hayes Agnew 54	.....	Neuralgia.	.....	.....	Median.	Temp. relief.	
3	Boldt	f. 26	Neuralgia left leg and thigh.	2 years.	.....	Ant. crural.	Cured.	See Appendix.
4	Le Dentu	m.	Facial neuralgia.	5 years.	Nov. 2, 1881.	Languid.	Cured.	
5	Le Dentu	f.	Facial neuralgia.	.....	.....	Languid.	Cured.	
6	Esmarch 39	.....	Neuralgia.	.....	.....	Peroneal.	Cured.	
7	Esmarch	m.	Neuralgia of testicle.	.....	.....	Ext. spermatic.	No relief.	The neuralgia followed castration.
8	Finlay 56	.....	Neuralgia.	.....	.....	.....	.....	
9	G. M. Hammond 42	f.	Hemiplegic neuralgia.	7 years.	.....	Left ulnar.	Cured.	Hemiplegia remained, but pain was entirely relieved.
10	Hildebrand 14	m. 32	Neuralgia of arm.	.....	.....	Brachial plexus.	Cured.	
11	Keleff 57	f. 35	Intercostal neuralgia.	.....	.....	4th, 5th and 6th intercostals of r. side.	Cured.	
12	Küster 47	.....	Neuralgia.	.....	.....	.....	.....	
13	Küster 47	.....	Neuralgia.	.....	.....	.....	.....	
14	Langenbuck ... 39	.....	Brachial neuralgia.	.....	.....	Brachial plexus.	Partial relief	
15	Langenbeck 39	.....	Brachial neuralgia.	.....	.....	Brachial plexus.	Partial relief	
16	Langenbeck 39	.....	Brachial neuralgia.	.....	.....	Brachial plexus.	Partial relief	
17 to 21	Langenbeck 44	.....	Neuralgia.	.....	.....	.....	Cured.	
	Langenbeck 44	.....	Neuralgia.	.....	.....	.....	Cured.	
22	Maag 8	.....	Neuralgia and contracture thumb and fingers	.....	.....	Median.	Cured.	Caused by a punctured wound in the hand.
23	Morton and Cox. 59	f.	Neuralgia of arm.	.....	.....	Ulnar.	Cured.	
24	Morton and Cox. 59	m. 32	Neuralgia of foot.	4 years.	.....	Sciatic and int. poplit.	Failed.	
25	Nussbaum. 60	m. 20	Intercostal neuralgia.	.....	.....	.....	Failed.	8th, 9th and 10th intercostals of each side stretched.
26	Omboni 61	.....	Neuralgia.	.....	.....	Brachial plexus.	Cured.	
27	Purdie 28	.....	Neuralgia index finger.	.....	.....	Digital nerves.	Cured.	

(4) *Miscellaneous Neuralgic Affections.—Continued.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
28	Schüssler.....47	f. 53.	Occipital neuralgia.	3 years.	.....	Occipitalis major.	Cured.	Nerve exposed where it passes through the trapezius; sheath thickened and injected, stretched in both directions; few attacks of pain during first 3 days; none afterward; wound healed by first intention. The disease had affected the right half of the occipital region.
29	Spence 31	.....	Neuralgia index finger.	7 years.	June 30, 1879.	Digital nerves.	Cured.	Patient had a whitlow on index finger, which became contracted; paroxysmal pain; nerves of finger stretched on a blunt hook.
30	Vogt 62	f.	Neuralgia.	10 years.	.....	Ulnar.	Cured.	

TABLE B.

Spasmodic Affections. (1) *Mimic Spasms.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Baum 63	f. 35	Tic non douloureux de la face.	6 years.	1878.	Facial.	Cure.	
2	Benedikt 64	.....	Tic non douloureux de la face.	.....	.....	Facial.	Cure.	Long-standing paralysis with secondary *tic*. Nerve degenerated. Operation completely relieved the *tic*, and the paralysis began at once to disappear.
3	Davidson.....11	f. 53	Tic non douloureux de la face.	1 year.	Nov. 24, 1881.	Infra orbital.	Cure.	Twitching of lids, sclerotitis and hazy cornea; disappeared after the stretching.
4	Eulenberg 65	.....	Tic non douloureux de la face.	.....	.....	Facial.	Cure.	Temporary paralysis.
5	Eulenberg 3	.....	Tic non douloureux de la face.	.....	.....	Facial.	Cure.	Temporary paralysis (5 months).
6	Godlee 66	m.	Tic non douloureux de la face.	.....	.....	Facial.	Cure.	Temporary paralysis.
7	Godlee 67	f. 72	Tic non douloureux de la face.	6 years.	.....	Facial.	Cure.	Temporary paralysis.
8	Germon 68	.....	Tic non douloureux de la face.	.....	.....	Facial.	Cure.	Temporary paralysis.
9	Hahn 44	.....	Tic non douloureux de la face.	.....	.....	Facial.	Slight imp.	No relapse of spasm for 6 months.
10	Hahn	.....	Tic non douloureux de la face.	.....	.....	Facial.	Great imp.	Temporary paralysis.
11	Putnam 69	m. 25	Tic non douloureux de la face.	3 years.	.....	Facial.	Cure.	
12	Schüssler.....70	f. 39	Tic non douloureux de la face.	8 years.	.....	Facial.	Cure.	
13	Southam 68	f. 59	Tic non douloureux de la face.	2 years.	March 28, 1881	Facial.	Cure.	Traction equal to 4 or 5 pounds; paralysis 5 weeks; affection originally caused by fright.
14	Southam	f. 32	Tic non douloureux de la face.	4 years.	Aug. 1, 1881.	Facial.	Cure.	Right facial; stretched at its emergence from stylo-mastoid for: paralysis for 4 weeks.

(2) *Torticollis, etc.*

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Annandale 30	f. 24	Spasmodic torticollis.	.....	.....	Spinal acces.	Cured.	Stretching and excision of spinal acc.
2	Blum..... 5	f. 18	Hysterical tremor.	4 months.	Aug. 4, 1880.	Right sciatic.	Cured.	
3	Hansen 71	f. 31	Spasmodic torticollis.	6 months.	.....	Spinal acces.	Cured.	Stretched and excised.
4	Hansen 30	30	Spasmodic torticollis.	18 months	....	Spinal acces.	Cured.	Stretched and excised.
5	Küster 44	.....	Spasmodic torticollis.	....	.....	Spinal acces.	Great relief.	
6	Morgan 30	.....	Spasmodic torticollis.	.....	.....	Spinal acces.	Cured.	
7	Morgan	f. 53	Spasmodic torticollis.	.....	.....	Spinal acces.	Failed.	*Lancet*, April, 1879.
8	Southam 68	f. 53	Spasmodic torticollis.	23 years.	Oct. 7, 1880.	Spinal acces.	Slight imp.	Subsequent excision. In these two cases the relief from stretching continued 5 or 6 weeks.
9	Southam	m. 14	Spasmodic torticollis.	10 years.	Oct. 23, 1880.	Spinal acces.	Improved.	
10	Studsgaard 71	f. 30	Spasmodic torticollis.	....	.....	Spinal acces.	Cure.	Stretched and excised.
11	Studsgaard	f. 31	Rotatory movement of the head.	.....	.....	Spinal acces.	Cure.	

TABLE C.

Contractures.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Berridge	20	Painful contracture of lower limbs.	.....	.....	Sciatic.	Failed.	No improvement up to the tenth day.
2	Callender.	36 m. 41	Painful contracture of arm.	6 years.	.....	Median.	Cured.	
3	Gartner	72 f. 38	Old hemiplegia with contracture.	....	.....	.....	Died.	Died from entrance of air in the veins.
4	Israel	44 child 3 yrs.	Spasms of limbs with contracture.	.....	.....	Both sciatics.	No improvement.	
5	Nussbaum	72 m. 23	Contracture of muscles of thorax and arm.	....	.....	Brachial plexus.	Cured.	

TABLE D.

Peripheral Paralysis.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Blum	73 m. 29	Traumatic paralysis of arm and hand.	3 months.	....	Radial and median.	Improved.	
2	Bomford	74 m. 40	Paralysis of hand and arm.	.....	Aug. 6, 1880.	Both ulnars.	Improved.	Anæsthetic leprosy. Anæsthesia and atrophy. Right ulnar could be felt as a cord (three times its usual size) under the skin. The left nerve was also thickened, but not uniformly. It ruptured on being stretched. The right hand recovered more rapidly than the left.
3	Callender	1 Inf't.	Infantile paralysis.	.....	.....	Ext. popliteal.	Failed.	
4	Israel	44 Inf't.	Infantile spinal paral.	....	.....	Left sciatic.	No imp.	
5	McLeod	75 m. 26	Paralysis of right hand and arm.	8 years.	.....	Ulnar.	Improved.	
6	Muralt	76	Paralysis of hand.	.....	.....	Radial.	Cured.	Due to fracture of humerus, which had united in a bad position.
7	Simon	77 m. 5	Paralysis of right leg.	3 years.	Aug. 5, 1880.	Right sciatic.	Great imp.	
8 to 37	Lawrie	1	Anæsthetic leprosy.	.....	.....	.....	Improved.	In these cases the sensation returned soon after the operation and muscular strength was regained.
38	Wallace	3	Anæsthetic leprosy.	....	....	.....	Improved.	
39	Wallace	3	Anæsthetic leprosy.	.....	.....	.....	Improved.	

TABLE E.

Epilepsy.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Czerny	3	Epilepsy.	.....	.....	Ulnar.	Slight improvement	Aura from ulnar nerve. No improvement, except that pot. brom. now had a good effect.
2	Gillette	3	Congenital epilepsy.	.....	.....	Median and ulnar.	Great relief.	The attacks diminished in frequency (from 90 to 18 monthly) and in severity. Aura disappeared. Temporary paralysis in region of ulna.
3	Morton	22 m. 40	Reflex epilepsy.	10 years.	.....	Brac. plexus.	Improved.	Aura. No loss of consciousness.
4	Nussbaum	78 m.	Reflex epilepsy.	.....	.....	Tibial and peroneal.	Cured.	Accompanied with club foot.

TABLE F.

Diseases of the Nerve-Centres.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Bastian	21 m. 39	Loc. ataxia.	3 years.	.....	Both sciatics.	Improved.	
2	Benedikt	64	Loc. ataxia.	.....	.....	Sciatic.	Improved.

55	Morton	m.	Athetosis.	From infancy.	Nov. 16, 1881.	Ulnar and median.	Improved.	Nov. 25, hand quiet for first time in the patient's memory. Jan. 25, 1882, improvement still persists.
56	Morton	m. 43	Paralysis agitans.	6 years.	Oct. 18, 1881.	Sciatic.	Great improvement.	Nerve dirty brown color, hard, and creaking under 40 lbs. traction. Feb. 1, 1882, walking improved; rigidity nearly gone.
57	Morton	m. 50	Lat. sclerosis.	10 years.	.....	Both sciatics.	Improved.	Two operations, June 11 and October 11, 1881.
58	Nicaise 20	f. 39	Hemiplegia, with contracture.	1 year.	.....	Left sciatic.	Failed.	
59	Nussbaum 83	m. 35	Traumatic myelitis.	11 years.	.....	Both crurals and sciatics.	Improved.	Spasms ceased, but paralysis persisted.
60	Remak 44	m. 30	Loc. ataxia.	.....	.....	Both sciatics.	No imp.	
61	Socin 3	m. 33	Loc. ataxia.	.....	.....	Both sciatics.	Improved.	Two operations; died four days after the second from multiple embolism, due to popliteal thrombus.
62	Sonnenberg....44	m.	Loc. ataxia.	.....	.....	Right sciatic.	Temporary imp.	Two days after operation, motion returned; anæsthesia and girdle pains disappeared; walk improved; relapsed after five weeks, when he fractured his patella; a temporary improvement again occurred.
63	Spencer 84	.....	Loc. ataxia.	15 years.	July 7, 1881.	Left sciatic.	Temp. imp.	
64	Osborn 22	m. 64	Loc. ataxia.	17 years.	Aug. 4, 1881.	Right sciatic.	Improved.	

Diseases of the Nerve-Centres.—Continued.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
65	Southam.....68	m. 51	Loc. ataxia.	3 years.	July 18, 1881.	Left sciatic.	Improved.	Lightning pains relieved; girdle pains and ataxic gait not improved.
66	Southam.....	m. 35	Lateral sclerosis.	.....	July 13, 1881.	Left sciatic.	Improved.	No return of pain six weeks after operation.
67	Tiersch.....85	m. 35	Spastic spinal paralysis	6 years.	.....	Both sciatics.	Temporary imp.	Very forcible stretching; improvement for fourteen days.
68	Tiersch.....	m. 28	Loc. ataxia.	4 years.	.....	Both sciatics.	Temp. imp.	Relapsed after three weeks.
69	Tiersch.....	m. 49	Loc. ataxia.	20 years.	.....	Both sciatics.	Temp. imp.	Relapsed after four months
70	Tiersch.....	m. 45	Loc. ataxia.	.....	.....	.....	Temp. imp.	
71	Wyeth 22	.....	Loc. ataxia.	7 years.	Sept., 1881.	Both sciatics.	Improved.	
72	Riedel.....98	.....	Injury to spine and cord	.....	.....	Both sciatics and crurals.	Improved.	Both sciatics and crurals were stretched at one sitting; sensibility and reflexes returned; locomotion improved.
73	Billroth 99	m. 29	Multiple sclerosis.	1 year.	July 14, 1881.	Both sciatics.	Slight improvement.	Patient did not rally from the operation: œdema of the lungs set in, and he died on the tenth day. A post-mortem examination showed spots of sclerosis in the brain and cord, especially in the region of the medulla; marked œdema of the lungs. Billroth thinks that the death was caused by the shock to an already-diseased central nervous system by the very forcible and repeated (ten times in each direction) traction upon both sciatics.
74	Mikulicz.....99	m. 46	Loc. ataxia.	16 years.	June 21, 1881.	Right sciatic.	Temp. imp.	Relapsed after four weeks.
75	Mikulicz.....	m. 44	Loc. ataxia.	6 years.	June 29, 1881.	Right sciatic.	Temp. imp.	
76	Mikulicz.....	m. 48	Loc. ataxia.	5 years.	June 16, 1881.	Right sciatic.	Temp. imp.	Relapsed after four months.
77	Mikulicz.....	m. 42	Loc. ataxia.	5 years.	July 5, 1881.	Both sciatics.	Temp. imp.	In these cases of Dr. Mikulicz, the effect of nerve-stretching was not the same as regards all the symptoms. The *ataxic* symptoms were unchanged in five cases; once there was a slight improvement, and twice the ataxia was increased. *Sensation* was not improved in four cases; in two there was temp. imp., and in two improvement persisted over three months. The symptoms referrable to the bladder and rectum were, in two cases, improved; in one case impotency was removed; in one case paralysis of the bladder supervened upon the stretching. In all the cases the "lightning pains" were relieved for a longer or shorter time.
78	Mikulicz.....	m. 50	Loc. ataxia.	.....	July 23, 1881.	Both sciatics.	No imp.	
79	Mikulicz.....	m. 45	Loc. ataxia.	3½ years.	Aug. 2, 1881.	.....	Slight imp.	
80	Mikulicz.....	m. 39	Loc. ataxia.	2 years.	Aug. 2, 1881.	Both sciatics.	Improved.	
81	Mikulicz.....	m. 40	Loc. ataxia.	5 years.	Sept. 4, 1881.	Both sciatics.	Improved.	

TABLE G.

Traumatic Tetanus.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1	Ashhurst.....34	.....	Traumatic tetanus.	.....	.....	Median and mus. spinal.	Failed.	
2	Bardeleben	.....	Traumatic tetanus.	.....	.....	Sciatic.	Failed.	
3	Clarke.....86	f. 24	Traumatic tetanus.	.....	.....	Sciatic.	Cured.	
4	Cowper..... 3	.....	Traumatic tetanus.	.....	.....	.....	Failed.	
5	Drake.....87	m. 28	Traumatic tetanus.	.....	.....	Sciatic.	Temporary imp.	Calabar bean used. Convulsions ceased for three days after stretching, then recurred. Died on twelfth day.
6	Fenger 3	m. 29	Traumatic tetanus.	.....	July 15, 1880.	Ulnar, radial, mus. spinal.	Failed.	Elbow crushed. Tetanus six days later. Arm amputated in middle of humerus and nerve stretched in the amputation wound. Next day paroxysms increased in frequency, and the patient died at night. No benefit from stretching.
7	Fenger	m. 43	Traumatic tetanus.	.....	July 11.	Median, ulnar, int.	Cure.	A rusty nail punctured palm of right hand. Four days later trismus and opisthotonos. Nerve stretched 14 days after injury. Immediate relief. Trismus and tetanus disappeared after four days. Paralysis of median and ulnar for 7 mos. Hyperæsthesia on dorsal side of 3d and 4th fingers for 3 weeks. Recovery. Calabar bean and chl. hy. also used.

Traumatic Tetanus.—Continued.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
8	Fenger	m. 55	Traumatic tetanus.		August 5.	Brachial plexus.	Slight relief.	Left forearm crushed. Amputation in lower third of humerus. Two days later paroxysms of pain, trismus and opisthotonos. Axillary plexus above clavicle stretched; but little relief. Two days later wound opened and nerves divided. Pain and opisthotonos stopped entirely for thirty-six hours. Relapse and death after two days.
9	Hahn 44		Traumatic tetanus.				Failed.	In one case the ulnar was stretched; in two cases the sciatic and crural were stretched.
10	Hahn 44		Traumatic tetanus.				Failed.	
11	Hahn 44		Traumatic tetanus.				Failed.	
12	Heath 88		Traumatic tetanus.				Died.	
13	Helmuth 89		Traumatic tetanus.					
14	Helmuth 89		Traumatic tetanus.					
15	Hutchinson 90	m. 22	Traumatic tetanus.	7 days.		Sciatic.	Died.	Relieved of pain.
16	Johnston 80		Traumatic tetanus.				Died.	
17	Klamroth 91		Traumatic tetanus.				Cured.	
18	Klin and Knie .. 1		Traumatic tetanus.	8 days.		Brachial plexus.	Died.	
19	Köcher 92	m. 45	Traumatic tetanus.	14 days.		Post tibial.	Died.	
20	Küster 15		Traumatic tetanus.			Crural.	Failed.	
21	Langton 3		Traumatic tetanus.				Died.	
22	Morris 29	child 7	Traumatic tetanus.	1 day.		Sciatic.	Died.	
23	Nankiwell 2		Traumatic tetanus.			Median.	Died.	One man was 25 and the other 42 years of age. The disease had existed 16 days and 8 days respectively.
24	Nankiwell 2		Traumatic tetanus.			Median.	Died.	
25	D'Ollier 93	m. 54	Traumatic tetanus.			Median.	Cured.	
26	Omboni 20		Traumatic tetanus.			Sciatic.	Died.	One case was a child of 7 years.
27	Omboni 20		Traumatic tetanus.			Sciatic.	Died.	
28	Owens 20	child 6	Traumatic tetanus.			Brachial plexus.	Died.	
29	Pepper 94		Traumatic tetanus.			Median radial.	Died.	Relieved for 2 days; died on third day.
30	Ramschoff 95	child 13	Traumatic tetanus.	11 days.		Post tibial.	Cured.	Calabar bean given four days with no effect. Stretching was followed by relief and gradual recovery.
31 to 34	Ratton 20		Traumatic tetanus.				1 cure. 3 deaths.	
35	Schneider 20	m.	Traumatic tetanus.				Died.	Five elongations.
36	Smith 88	m. 54	Traumatic tetanus.			Median.	Cure.	
37	Schede 82		Traumatic tetanus.				Failed.	
38	Sonnenberg 82		Traumatic tetanus.				Failed.	
39	Thomas 96	m. 23	Traumatic tetanus.			Median.	Died.	
40	Verneuil 80		Traumatic tetanus.			Ulnar and median.	1 died.	
41	Verneuil 95		Traumatic tetanus.			Ulnar and median.	1 cured.	
42	Vogt 3		Traumatic tetanus.			Brachial plexus.	2 cured.	One case injured palm of hand. On 4th day tetanus developed and increased; on 22d day the nerves of brachial plexus, which were tender on pressure, were stretched centripetally and centrifugally; the sheath was reddened and freely opened; immediately after operation the spasms ceased; he could open mouth and protrude tongue; ten days later, discharged cured.
43	Vogt 3		Traumatic tetanus.			Brachial plexus.	1 died.	
44	Vogt 3		Traumatic tetanus.			Brachial plexus.		
45	Watson 2	m. 16		3 days.		Brachial plexus.	Died.	
46	Watson 2	m. 35		2 days.		Brachial plexus.	Died.	
47	B. Watson	m.	Traumatic tetanus.				Died.	
48	Weir	m. 11	Traumatic tetanus.	1 day.		Ulnar.	Failed.	See Appendix.
49	Weir	m. 29	Traumatic tetanus.	1 day.		Post tibial.	Relieved.	See Appendix.
50	Wheeler 97		Traumatic tetanus.					

TABLE H.

Diseases of the Optic Nerve.

No. Case.	Operator.	Sex and Age.	Disease.	Duration of Disease.	Date of Operation.	Nerve Stretched.	Result.	Remarks.
1 to 7	Kummel 22		Neuritis and atrophy of optic nerve.			Optic nerve.		Two cases of neuritis, slightly improved.
	Kummel 22		Neuritis and atrophy of optic nerve.			Optic nerve.		
8	Wecker 20					Optic nerve.		Results not yet published.

The following letter from the distinguished Professor F. von Nussbaum was received at too late a date to be made available in the tables. I give the letter in full with its summary of fifty-two cases:

"MUNICH, May 23, 1882.

"DEAR SIR: With the kindest regards I inform you of the results of my operations in nerve-stretching.

"I.—I have stretched the sciatic thirty-five times. Six of these operations were done subcutaneously. The operation was done eleven times for tabes dorsalis, with very good results. Twenty-four times on account of neuralgia (twenty times with good effect, and four times with but little benefit).

"II.—I have stretched the intercostal nerves once in a case of neuralgia. The result was excellent for a time, but after six months relapsed.

"III.—In reflex epilepsy I have operated eleven times, always with very good results.

Five times the brachial plexus was stretched.
Four " " sciatic nerve " "
Once " tibial " " "
" " ulnar " " "

"IV.—Three times I have stretched the supra-orbital and infra-orbital nerves for neuralgia. The results were good. I have not, however, often made this operation, because I have always had most excellent results after resection of the supra-orbital, infra-orbital, lingual, and inferior maxillary nerves. In twenty-seven years I have made 242 resections of these nerves.

"V.—I have twice stretched the facial nerve in cases of clonic spasms. But little benefit resulted from the operations.

"Receive my compliments and the kindest regards of

"PROF. DR. T. RITTER VON NUSSBAUM,
"*Surgeon-General, Bavarian Army.*"

It is gratifying to observe that the addition of such a large number of cases does not change, but rather confirms the conclusions already reached as to the efficacy and proper sphere of the operation.

APPENDIX.

The following cases have not appeared in any of the medical prints and are appended to this paper:

CASE I.—Operated on by Dr. Wm. Pierson, Jr., Orange, N. J., and reported by Dr. George O'Gorman, House Surgeon at St. Michael's Hospital, Newark, N. J.:

An Irishman, aged thirty-nine, strained himself by lifting, and has ever since (three months before admission) had a severe pain in his leg. In the hospital, varied treatment by blisters, pot. iod., quinine, morphia, etc., was of no avail. On June 30th, eight

months after admission, Dr. Pierson cut down upon the sciatic in its upper part. The nerve was thoroughly stretched in both directions and the wound closed. There was a slight amount of inflammatory action about the wound, but it was easily controlled. The pain ceased gradually (two or three days) after the operation and has never since returned. A little stiffness of the limb followed the stretching, but it passed away after two or three weeks.

Dr. Carl Buttner kindly furnished the details of two cases of sciatica.

CASE II.—A man, aged forty, was admitted to Memorial Hospital, Orange, N. J., June 17th. He had been afflicted with the disease eight months, and had received the usual varieties of treatment, but without success.

June 17, 1881.—The right sciatic was exposed and moderately stretched in both directions. Ten days later he left the hospital and has remained well ever since.

CASE III.—Dr. Buttaer's second case was a German, aged thirty-six. The disease had existed for eight years, and for the last two years he had been entirely unable to work. The right sciatic was stretched on December 17, 1881. The sheath of the nerve was highly congested, but the nerve itself was of normal whiteness. No adhesions were found. Greater traction was made than in the previous case, and the elongation was so great that the loop of the nerve protruded beyond the lips of the wound. The wound healed readily, the pain ceased, and the patient has been perfectly well ever since.

CASE IV.—Dr. Dougherty, Newark, N. J., operated on a case sciatica at the Soldiers' Home in Newark. Partial relief only was obtained, and a second operation is contemplated to complete the cure.

CASE V.—Dr. D. Hayes Agnew, of Philadelphia, reports two cases of neuralgia, in one of which the sciatic nerve, and in the other the median nerve was stretched. In both cases only temporary relief followed the operation.

CASE VI.—Dr. W. A. Hammond, through the courtesy of his son, Dr. G. M. Hammond, furnished me with nine cases, seven of which were hitherto unpublished. Four were cases of sciatica of several years' duration, accompanied with atrophy of the limb. The sciatic was stretched, and a permanent cure followed in all cases. Four were cases of locomotor ataxia. Two were greatly relieved; one was temporarily benefited, and the fourth received no benefit; the symptoms were aggravated after the operation. One case of antero sclerosis received temporary benefit from the elongation of the sciatic. Dr. Hammond has always exposed the nerve at junction of upper and middle third of the thigh, and made traction in both directions enough to elongate the nerve about one inch. He regards the operation as of "considerable value."

CASE VII.—Dr. G. M. Hammond reports a case of locomotor ataxia of five years' duration. The sciatic was stretched in the lower third. There has been no improvement up to the present time—five months after the operation.

Dr. R. F. Weir, of New York (through his house-surgeon, Dr. F. N. Townsend), reports two cases of tetanus in one of which the post tibial was stretched, and in the other the ulnar. In one case slight relief was afforded, though both cases terminated in death.

CASE I.—Michael Cody, aged twenty-nine. July 15, 1879, patient admitted for small lacerated wound of foot, received twenty-four hours before. Full Lister used.

July 21st.—Complains of stiffness in muscles of neck and jaws; can with difficulty open mouth; wound looks well.

Treatment.—Chloral hydrate in large doses.

July 22d.—Frequent and violent tetanic spasms; tonic in character.

Operation.—Posterior tibial nerve stretched under full Lister. Several hours after operation, seemed easier; spasms fewer in number.

10 P.M.—Breathing rapid, pulse feeble; patient in an unconscious condition, and at 3 A.M. of July 23d died in a spasm.

CASE II.—Henry O'Neill, aged eleven. July 7, 1881, patient received a wound on the hypothenar eminence while shooting blank cartridges with a toy pistol. Wound healed rapidly. Last night (July 11th) was seized with severe convulsions, patient being conscious but with pain in neck. On admission had spasms, with trismus and opisthotonos, and cyanosis.

July 12th.—*Operation.*—Esmarch's bandage and full Lister used; ulnar nerve stretched. No effect from operation on frequency or severity of spasms, and, at 10.30 P.M., patient died in severe spasm.

The following letter from H. J. Boldt, M.D., contains his notes of six cases:

"CASE I.—J. S——, aged forty-five. Tabes dorsalis, second stage, the disease dating back about six years. Patient has severe lancinating pains, radiating from the origin of the lumbar nerves, down the thighs and legs, epigastric region, and abdomen. At times the pains were so severe that the patient cried. All the usual remedies having been tried without any benefit, the sciatic nerve was stretched by Dr. Wm. A. Hammond, at the University Medical College Clinique. The patient was much relieved after the operation, and *walked* home from the college, a distance of nearly three miles, without the least fatigue. He remained free from the pains (ataxic gait remaining) for about three months, when gradually his former condition appeared again, and he is at present suffering as much as prior to the operation, *i.e.*, about one year ago.

"CASES II. and III.—Operated upon by me. Have taken a similar course. The disease and severity of them were the same as in Case I. (Nerve stretched, sciatic.)

"CASE IV.—Mrs. S——, wife of Case I., aged forty-five. Third stage of locomotor ataxia. Disease dates back about twelve years. The patient has not been able to leave her bed for over three months; pains excruciating; she could not bear the slightest touch on the abdomen or anterior part of the thighs. All remedies having failed, I resorted to the stretching of the anterior crural nerve. Results were satisfactory, and remained so as far as the pains were concerned; otherwise a failure. (I believe that this was the first time the operation was performed in New York for tabes.)

"CASE V.—W. M——, aged fifty. Second stage locomotor ataxia, disease dating back about eight years. Suffered the usual pain, and had accompanying disturbance of bladder. Stretched anterior crural nerve, with result of immediate subsidence of the pain and bladder symptoms, ataxic gait remaining. Whether the relief of pain is permanent I am unable to say, not having heard from the patient for over eight months.

"CASE VI.—Mrs. H——, aged twenty-six, has been suffering with pains in her left hip, thigh, and leg

about two years. Suddenly, the pains increased so much in intensity that she was unable to bear the slightest movement; to use her expression, 'I am suffering the pains of hell continuously.' For four days I tried to relieve by different measures, but without effect; she was rapidly losing ground. At the same time a very severe cough set in, which was purely reflex. Stretched the anterior crural nerve on the affected side, and from that time the patient was free from all pain and cough, and continued so.

"From the above cases I come to the conclusion that the stretching of nerves is only to be advised for the relief of symptoms, and then the result is variable. In my opinion the stretching of the anterior crural nerve is of more benefit in cases of tabes than the sciatic. The force used on the anterior crural was from fifteen to twenty pounds. The sciatic was stretched in my cases in the lower third of thigh.

"Very truly yours,

"H. J. BOLDT.

"TO DR. CHANDLER."

Progress of Medical Science.

LESION OF THE ISLAND OF REIL.—An interesting case is given by Bourneville and Bonnaire, in which a man, aged thirty-four, was suddenly seized with left hemiplegia (*Archives de Neurol.*, No. 8). The attack took place twenty years before his admission into Bicêtre. Six years after the paralytic seizure the patient became subject to epileptic attacks. When the man came under observation he was suffering from left hemiplegia, with contracture; the arm and leg were a good deal wasted, and there was a perforating ulcer on the sole of the left foot. The tendon-reflexes on the paralyzed side were much exaggerated, and there was spinal trepidation. There was no disorder of sensibility, but the intellect was much impaired. The necropsy showed, on the right side, atrophy of the posterior part of the third frontal convolution, of the two ascending convolutions of the globule of the gyrus angularis, and of the entire island of Reil. The first and posterior parts of the second temporo-sphenoidal convolution were also involved. The island of Reil was replaced by a kind of gelatinous membrane of reddish color. The parts above named were simply atrophied, and presented no change of color. The right corpus striatum and optic thalamus were considerably reduced in volume. Secondary descending degeneration was visible to the naked eye in various regions through which the pyramidal tract passed.

CALCULUS OF THE BLADDER IN AN INFANT.—Dr. J. W. Troitzky relates, in *Wratsch*, No. 37, 1881, the case of a child, one month old, which was brought to him with the following history: In other respects perfectly healthy, it cried loudly, about twice a week, on attempting to pass urine. The mother accidentally discovered that the flow of urine became free, and the child was relieved, when she held its pelvis and feet higher than the head. It first cried during micturition when it was eight days old. Twenty-four hours before Dr. Troitzky saw the child the difficulty had returned and could not be removed by the usual manœuvre; the flow of urine was quite arrested. The bladder was distended with urine, and a calculus was detected in the urethra, about the middle of the penis. All attempts to remove it were fruitless. Dr. Troitzky then injected a few drops of almond-oil into the urethra, and easily pressed the stone toward the orifice; after the dilatation of which, the calculus was removed. It weighed a quarter of a gramme (nearly four grains), was eight millimetres long and four wide, and consisted of urates arranged in layers. The urine contained an abundance of crystals of uric acids and urates. The formation of the calculus must have commenced during intra-uterine life. The child's parents were healthy; the grandfather on the father's side had suffered from calculus.

TREATMENT OF INFANTILE PURULENT PLEURISY.—Dr. Martial Durand has communicated a very complete study on this subject to the Society of Medicine and of Surgery of Bordeaux, which terminates in the following conclusions: 1. Aspiratory puncture, either simple or followed by injections, is a bad method of treatment, of which the duration is frequently much prolonged, and which scarcely ever dispenses with the necessity of having recourse to other means. 2. The method of treatment by drainage-tubes, and especially by Potain's siphon, has almost all the inconvenience of pleurotomy, since it does not thoroughly preserve from the entrance of air, without having its advantages, since it does not allow the exit of the intra-pleural detritus. 3. M. Durand believes that the objections to the entrance of air into the pleura have been much exaggerated. It does not seem to him that this is dangerous if the pus flow continuously, and if the air be not imprisoned. 4. The operation for empyema seems to him to be the best of methods when the diagnosis is very clear. With this proceeding, the disease is, perhaps, less prolonged, but it is desirable that this operation should be made use of before the patient has fallen into a state of cachexia. The operation gives good results, and would give better if the general condition were good, and with the use of antiseptic methods.

RENAL CALCULUS IN CHILDREN.—The occurrence of renal calculus in children, Dr. Eustace Smith thinks to be more frequent than is usually supposed. Uric acid is the commonest constituent of the concretion. This proteid derivative is often excreted in excessive quantity; an apparent increase in the amount being due to a diminished secretion of water, or an increased acidity of the urine, while a real excess frequently results from large quantities of food, or increased tissue-metabolism. This tendency to lithic acid formation may be hereditary, as in the gouthy diathesis, and all conditions that interfere with the assimilative processes tend to a precipitation of uric acid in some part of the urinary apparatus, either as infarctions in the tubules of the pyramids, or in the pelvis of the kidney. Besides uric acid, oxalate of lime concretions are not uncommon in children; and sometimes small calculi of urate of ammonia or soda, occasionally a nucleus of uric acid, may be encrusted with urates or phosphates, the latter indicating the existence of vesical irritation. Urine that may be thick from lithates is passed without any distress to the child; but excess of uric acid determines frequency of micturition, signs of pain in the urethra, and very often nocturnal incontinence, while the passage of the sharp crystals along the renal tubules is a frequent cause of hæmaturia. Indeed, this latter symptom in children is usually to be attributed to the cause under consideration. Examination of the urine in these

cases often gives a negative result. Calculus may exist in the kidney without giving rise to symptoms of any kind. Between the attacks of hæmaturia, the urine may contain neither blood nor albumen, and, unless uric acid be actually passing, it may redden litmus paper but faintly. Sometimes the irritation produced by the presence of the calculus in the pelvis of the kidney may set up pyelitis, the stone then usually becoming enlarged by deposition of phosphates upon its surface. The passage of the concretion along the ureter seems to be attended with less pain than in the adult, though serious consequences will follow its impaction, such as contraction of the passage, and even hydronephrosis. While it is far from uncommon for children to pass quantities of uric acid sand, a coincident hæmaturia is by no means so frequent; and this seems due to the fact that the acid is commonly deposited from the urine in the bladder itself, and not at a higher point in the urinary tract. In the case of children, it may be laid down as a rule that renal hemorrhage, occurring in a child otherwise healthy, and accompanied by no symptoms or by hemorrhage from other parts of the body, is in the majority of cases to be attributed to the irritation of crystalline masses in the tubules, calyces, or pelvis of the kidney. Where there is evident disposition to excessive formation of uric acid, the diet should be light and plain, and the meat and farinaceous constituents carefully proportioned to the digestive powers; alkalies should be given, and, if there be hemorrhage, perfect rest in bed enjoined. Styptics are rarely required.—*London Medical Record*, July 15, 1882.

Multiple Cirrhosis of the Kidneys, Liver, Lungs, Etc.—While carrying out his researches upon primary cirrhosis of kidney in Professor Ostroumoff's clinic, in Moscow, Dr. Langovoi (*Med. Obozr.*, Jan., 1882) met with a series of cases in which, side by side with the affection of the kidneys, there existed similar changes of the heart, liver, lungs, spleen, peritoneum, etc. The author gives a detailed clinical account of four such cases, adding some interesting results of the post mortem examination. The microscope revealed very extensive and profound alterations in the vessels of all organs investigated. They were these: 1. Endarteritis obliterans, which either completely closed or only considerably narrowed the lumen of the vessel; 2. Mesoarteritis, shown by an immense thickening of the muscular coat of the artery; and 3. Periarteritis, with hypertrophy of the adventitia, and formation of dense connective tissue radiating from the vessel in all directions. Besides these vascular changes, the kidney showed great increase of connective tissue, obliteration of the glomeruli, granular disintegration of the epithelium of the tubuli contorti; the liver, intense proliferation of the interlobular connective tissue; the uterus, hypertrophy of the fibrous tissue and atrophy of muscular fibres; the ovaries, cirrhosis, with atrophy of follicles; the spleen, enormous thickening of the trabeculæ, and an infarct with a central vessel containing the organized thrombus; the submaxillary glands, hyperplasia of the connective tissue; the heart, very pronounced increase of connective tissue, and atrophy of the muscular elements, both in the papillary muscles and in the walls; the lungs, compression and narrowing of the alveoli, with great hypertrophy and leucocytic infiltration of the interstitial tissue. Discussing the question whether all those changes simultaneously affecting the organs of all kinds are only accidentally coincident, or produced by a common exciting cause, the author follows the teaching of Sir W. Gull and Dr. Sutton, and attributes the development of multiple cirrhosis of the viscera to primary arterio-capillary fibrosis. He found considerable vascular fibrosis, even where the changes of connective tissue in an organ were only slight and incipient. In his opinion the increase of blood supply, resulting from the beforementioned vascular alterations, necessarily leads to proliferation of connective tissue in the organs affected.

Amyloid Kidney without Albuminuria.—Dr. J. Straus (*L'Union Médical*) has published a paper on the above subject, and submits the following conclusions: 1. In certain cases of amyloid degeneration of the kidneys albuminuria may be constantly absent until death. 2. The absence of albuminuria is due, on the one hand, to the absence of a deep lesion (interstitial or epithelial) of the kidney, and, on the other hand, to a special localization of the amyloid degeneration. This, in such cases, bears chiefly upon the *vasa recta* of the medullary substance, and implicates in a minor degree the glomerular vessels. 3. From a clinical point of view, if in a phthisic or an inveterate syphilitic, or a subject of chronic osseous suppuration, etc., we find enlargement of the spleen and of the liver, but *without albuminuria*, we are not justified on this account in rejecting the idea of amyloid degeneration of the viscera, nor even in absolutely denying amyloid degeneration of the kidneys. 4. Those authors who date the beginning of amyloid degeneration in the economy from the moment at which they observe the presence of albumen in the urine, commit a double error, (*a*) because amyloid degeneration is far from beginning always by invading the kidneys; on the contrary, the spleen and the liver are habitually the first to be attacked; (*b*) because the kidney itself may be suffering from amyloid degeneration without albuminuria being present. It is then necessary to mistrust calculations by which it has been sought to fix the possible duration of life in subjects afflicted with amyloid cachexia, by making this date from the first appearance of albuminuria.

Rupture of the Hepatic Duct.—An interesting case of rupture of the hepatic duct is reported in the *Lancet* (May 6, 1882) by Mr. John Freeland, of Antigua. The patient was a black woman, sixty-five years of age, who had been suffering with intermittent fever, gastric disturbance, and retching. In one of the vomiting spells she experienced great pain, which, being relieved by an opiate, soon returned, and was attended by a tympanitic and tender abdomen. After death, which occurred in collapse about eight hours later, the cavity of the abdomen was found literally filled with blood and bile, the intestines inflamed and gangrenous in spots, and general peritonitis. The gall-bladder was found empty; the hepatic duct was lacerated, and in places contained pouches in which gall-stones were encysted. One of these bags was pervious, and permitted a leakage of bile into the peritoneal cavity, except when obstructed by a gall-stone which it held. This opening had probably existed for years. The former one was surrounded by evidences of recent inflammation, and, without doubt, caused the fatal result. The spleen was deeply stained with bile. The other viscera did not show such decided coloration.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 9, 1882.

RECENT LITERATURE OF TUBERCLE.

THOROUGH as have been the experimental investigations of Villemin, Toussaint, Bouley, Bollinger, Klebs, Hugues, Vallin, and other distinguished European scientists whose inquiries have graced the literature of medicine during the last three years, as to the contagiousness of tubercular disease, the mode and vehicle of its propagation, and the possible relation of tubercle in the inferior animals to tubercular phthisis in man—it is still an unsettled issue to what extent the ingestion of meat and milk from tuberculous cattle is concerned in the development of the disease. The question is one of primary interest to the science of public medicine; for, if it were proved beyond a doubt that, under ordinary circumstances, the consumption of meat from tuberculous beeves or sheep, or of milk from tuberculous cows, is capable of producing the disease in man, the result would be an immediate revolution in alimentary hygiene; a revolution whose pecuniary would be hardly less than its sanitary and scientific interest and one of whose direct consequences would be the condemnation of fifteen beeves in every hundred slaughtered for the market, according to competent veterinary authorities, and of fifteen cows in every hundred concerned in the production of our daily milk supply. It is of the highest importance, therefore, that the question should be cautiously handled, the experiments and observations carefully verified, and the ultimate decision one that cannot be reversed or modified. If, as is believed by many able European physicians and veterinarians, the prevalence of tubercular disease in cows concerned in our milk supply, and in animals slaughtered for food, is a leading factor in the propagation for a scourge whose ravages are responsible for fifteen per centum of the deaths recorded by vital statistics; or if, as more moderate scientists are persuaded, it is a subordinate but still a real factor in the etiology of tubercular phthisis, then, whatever may be the pecuniary loss to cattle producers, the condemnation of such animals is of pressing moment to public health, and the legislation thereto essential should be secured without delay. But the fact must be incontestably established by thorough investigation before appealing to the legislature; for it is in the highest degree unlikely that a measure of such unpopularity with a large section of the community, and involving such pecuniary loss to dairymen, would be entertained by a legislative body upon probabilities alone, however imperious and convincing.

In Germany, taking this view of its practical moment, the subject has not been left to the decision of private observers; but the Imperial Minister of Agriculture has appointed a commission composed of pathologists of the highest reputation, with instructions to inquire experimentally into the question, whether the disease can be communicated by milk from tuberculous cows or by meat from tuberculcus cattle, and if so, under what conditions. In France, also, the institution of such a commission by the Minister of Agriculture is agitated, and both the Institute and the Academy of Medicine have the matter under consideration; while some of the ablest memoirs that have marked the literature of tuberculosis have been read before the Academy of Sciences. There is in this country a National Academy of Sciences as well as an American Medical Association, and an Institute (the Smithsonian); but it has not apparently occurred to either to evince concern in a question of greater importance to the United States than to Germany or France, owing to our vast cattle-producing areas and our present and prospective relation to the cattle marts of the world.

It was M. Villemin who first stated that the ingestion of tuberculous matter by healthy animals and its inoculation upon them were capable of specifically reproducing the disease. It was urged, in answer to his assertion, that the introduction of other septic material into the tissues of healthy cattle is capable of determining tubercle; and this was experimentally proved, although the result did not follow the cause with that unerring regularity and certainty which Villemin had described in his paper. Toussaint came to the rescue of his distinguished confrere, by showing that tuberculosis could be produced in pigs—animals very refractory to that disease—by the inoculation of only two cubic centimetres of juice expressed from the muscles of a tuberculous cow. He also caused tuberculosis in the dog, by injecting a few drops of blood from the finger of a phthisical man into the cellular tissue of the animal; and finally determined tubercle in the hog by the ingestion of tuberculous meat and milk. A transcript of his experiments

was read before the Academy of Sciences, and formed the starting-point of the large body of literature that the subject now presents.

The theory that the disease is propagated by a special bacterium present in tuberculous matter, and in the milk, tissues, and fluids of phthisical animals, was first advanced by Professor Klebs, who claimed that he had discovered such a bacterium, and had proved by experiment that, unless it was present in the liquids used for inoculation, the injection of the blood or juices of tuberculous cattle was incapable of causing tubercle. He furthermore declared, in the same remarkable paper, that he had been successful in the cultivation of this organism, according to the method of M. Pasteur, and had succeeded in producing tubercle by inoculating animals with it after such cultivation. This striking memoir, which really anticipated by several years an aspect of the subject that has lately attracted universal attention in the hands of other observers, was productive of no immediate consequences; the statements of the author were doubted in some quarters and denied in others; like most daring innovators, his results, though since verified in important particulars, reacted against the credibility of their author: for it is at exceeding risk of personal prestige that one ventures upon the record of facts subversive of current scientific doctrines. Wherefore, science, having its orthodoxy as rigid in its way as that of theology, it is the habit of many distinguished scientific men to suppress facts when they find them in conflict with prevalent theories. More to the point, though of dubious morality, is the experiment of the three Greek physicians, Deuset, Tareskera, and Zallouis, who inoculated a man with healthy lungs, dying of slow gangrene of the left leg, caused by obliteration of the femoral artery, with a quantity of the sputa of a phthisical patient. The operation was performed on the upper part of the left thigh, and in about three weeks auscultation disclosed a perceptible murmur at the apex of the left lung. The man lived thirty-eight days, then died of the progressive gangrene. The autopsy revealed the presence of twenty-six newly formed tubercles in the upper part of the right lung, and two near the apex of the left.

It would be an unpardonable cumbering of space to review the development given within the last few months to the bacterium hypothesis of the propagation of tubercle first advanced by Klebs, and resuscitated by later investigators after the original paper had apparently been forgotten—resuscitated, too, it may be added, without a passing reference to his work. The best mode of demonstrating tuberculous bacteria has been fully discussed by European microscopists, in articles that have been reprinted here, and are familiar to the medical reader. The facts which seem to be proved are that tubercular disease in animals is contagious; that it is communicable experimentally from the diseased to the healthy animal by the ingestion of meat or milk as well as by that of tubercle itself; that it may be communicated by inoculation with the blood, the tissue juices, or the sputa, as well by means of infusions of tuberculous matter; and that, in a few cases at least, tubercle in man has been traced, with a reasonable degree of certainty, to consumption of the meat and milk of tuberculous cattle.

But little has been done in this country in this aspect of the literature of tuberculosis. Some three years ago a committee consisting of Prof. J. M. Heard, Prof. W. P. Worster, and Prof. F. G. Fairfield, was appointed by President Rawson of the New York College of Veterinary Surgeons, with a view to verify the results of European inquiry and to investigate the special aspects of the subject as presented here. In the report of the commission, which has just been submitted, the results arrived at by European observers are passed over very lightly; but with the qualification that some forms of tubercle are not communicable by inoculation, while others undoubtedly are; in other words, that there are malignant and non-malignant forms of tubercular disease; not to be distinguished from each other, however, by the presence or absence of bacteria—for bacteria are present in both. The investigations of the committee have been specially directed to two important questions: First, whether tuberculous milk and meat can be distinguished from the milk and meat of healthy animals; and, secondly, the origin of tuberculous matter in the animal organism. On the first point, the conclusion is that the milk of tuberculous animals can be distinguished from healthy milk, partly by reference to physical qualities, and partly from microscopic tests. But as respects the meat of tuberculous animals, this is not the case, while, as concerns the blood, the advanced stages of the disease can be identified with tolerable certainty. The committee finds that tubercular disease is marked by a process of cell-decomposition, in which the first step is granulation of the cell contents, and the second rupture of the cell-pellicle and escape of the granular bodies. This decomposition is particularly marked as relates to the colored corpuscles of the blood, involving often as large a proportion as one in every fifteen or twenty, and producing in the later stages a rapidly progressive anæmia. The minute bodies into which the diseased corpuscle is thus resolved are real living organisms, possessing all the activities of protoplastic life, and constitute the germs of the bacteria observed in fully developed tubercle. It is thus credible that the introduction of such germs into the healthy circulation may determine a true tuberculous formation, by determining a true tuberculous condition of the blood; and so

far the inquiries of the college committee sustain the conclusions of Klebs. A tubercle, then, may be defined as the equivalent, actually, not theoretically alone, for a given amount of cell-destruction. More than this, the committee finds from many experiments that the process of granulation above described is the true mode of cell-death in all tissues, animal and vegetable. Thus, while leprosy is marked by one type of cell-degeneration, cancer by another, anthrax by another, and so on, tubercle is distinguished by direct cell-death as a progressive process; and quantitatively considered a given, mass of tuberculous matter is the direct physical equivalent of a given amount of cell-destruction, or rather, of the death of a given number of cells.

The report of the committee is in this particular a strikingly original contribution to the literature of tuberculosis; but it must not be forgotten that the verification of a large body of observers is essential to establish a pathological doctrine of such significance as this, which implies that the minute bacteria associated with various diseases all have a common starting-point in the destruction or metamorphosis of cells; that is, either in the granulation and splitting up of the cell-contents into minute bacterial organisms, or in the transformation of the cell protoplasm as a mass into larger organisms. The first takes place in tuberculous degeneration, the second in the production of anthrax rods.

It is not to our purpose to enter upon any critical analysis of the statements contained in the report. In the nature of things their verification or denial will follow in due season. If subsequent inquiry should establish them, they will take their place as a step in advance in the pathology of tuberculosis; and to time, which tests and sifts all scientific doctrines, their fate must be committed.

DR. BUCKNILL ON THE MENTAL CONDITION OF GUITEAU.

In the current number of *Brain* is an article by Dr. J. C. Bucknill upon the mental condition of Charles Julius Guiteau. Dr. Bucknill has probably no superior in Great Britain as a student of, and expert in, mental diseases. Certainly, no one will be impudent enough to class him as either dishonest or an ignoramus. His opinion, free, as it must be, from any local bias, claims more than usual weight and attention.

It is naturally a source of satisfaction to find that he sides with the general judgment in considering Guiteau to have been sane and responsible. Dr. Bucknill comes to this conclusion after a careful study not only of Guiteau's history and trial, but of the special pamphlets put forth by the gentlemen who believed in his insanity. It will be remembered that these pamphlets have been so numerous as to call to mind very strongly the saying that "error is ever talkative."

In the face, however, of all this argumentation, Dr. Bucknill reaches the conclusion we have mentioned. His article is not a long one, and does not attempt to treat the question exhaustively.

It is shown in the first place, how entirely the American pamphleteers have failed to indicate what form of insanity Guiteau possessed. The futility of attempting to classify it as an example of the "reasoning mania" of Pinel, is abundantly proven, if any proof were necessary. Such careful writers as Folsom and Channing acknowledged their perplexity and furnished no conclusions for criticism to attack.

The stress laid by some experts upon the value of hereditary influence is deprecated by Dr. Bucknill. He even goes so far as to say that for legal purposes hereditary influence might just as well be counted out. It is true that the oft-repeated statement that Guiteau's hereditary history was full of insanity is a violent exaggeration.

It has been insisted that, on a number of occasions, Guiteau was subject to delusions. The attempts to start, and subsequently to buy, a paper are instanced. His inspiration to assassinate the President has also been referred to as a delusion, using the term in its technical sense. Guiteau said, "If the jury believe that I believed I was inspired to remove the President, then they must find me insane—in law, but not in fact." Guiteau's inspirations and delusions, however, were unquestionably, as Dr. Bucknill shows, the outgrowth of his education and character, not of any disease. The inspiration by God to good actions, by the devil to bad actions, is the creed of the Oneida Perfectionists. It was the creed of Guiteau's father, and the one upon which Guiteau had been nursed and nourished.

It was but natural that he should believe so great a deed as the murder of a President to be inspired, just as he had previously believed himself inspired to found a journal.

In conclusion, we would add that the *Journal of Mental Science*, edited by Dr. Tuke, in an editorial review, takes ground similar to that of Dr. Bucknill.

Thus, as we become farther removed from the time of trial, expert opinion is siding with that first expressed by the mass of conservative men. It does not follow, because a nation is excited and aroused, that its feelings are wrong or its judgment incorrect.

THE SHARP SPOON IN SURGERY.

Dr Pfuhl has given an account in the *Deutsche Militärzth Zeitschrift*, of the many uses to which a specially devised spoon with sharp cutting edges may be applied in surgery. This instrument is not unknown to surgeons, and the serrated spoon in particular has been much employed in America for the removal of uterine polypi. Dr. Pfuhl has, how-

ever, studied the capabilities of the sharp spoon more than any one else, and now formulates the indications for its use in a manner that claims the attention of surgeons.

The spoon is not a clean cutting instrument, and it generally leaves some irritation behind. It is painful, and anæsthetics must, as a rule, be employed along with it. It causes considerable hemorrhage also, and, where practicable, Esmarch's bandage is first applied. Its advantages are that morbid tissues can be more perfectly removed. Especially is this the case in malignant growths, in ulcers, and in some forms of skin disease. Upon the skin it is most indicated in chronic torpid ulcers, especially those of the legs. Here the base of the ulcer must be carefully scraped until perfectly healthy tissue is exposed. The hard edges need often to be snipped off with scissors. The after application of a rubber bandage then helps to secure a good result. In scrofulous and syphilitic ulcers and abscesses, the spoon has been used with a most happy effect. The author also recommends it in lupus and epithelioma of the lip. He believes that it cleans the healthy tissue better than can be done by any other method. In such skin diseases as squamous eczema, acne simplex, and sycosis, the spoon is also effectual.

In diseases that affect the deeper layers of the skin, such as furuncles, carbuncles, mammary abscesses, and even in wounds with diphtheritic deposits, Dr. Pfuhl thinks that by the use of the spoon peculiarly good results can be obtained.

In diseases of the glandular organs, such as purulent inflammation of lymphatic glands (buboes, tubercular glands, etc.), the spoon is employed, the whole diseased tissue being thus easily removed.

The application of the sharp spoon to diseases of mucous membranes is not so extensive, still it is of much value in soft cancers, adenoid vegetations, etc.

Bardenheuer has used it in trachoma of the lids. In gynecological practice it may be modified so as to act like a curette. Volkmann and Bardenheuer as well as the author have used the instrument in question in diseases of the bones and joints.

Our author gives evidence quite sufficient to show that the sharp spoon is a useful addition to the armamentarium of the surgeon.

THE VALUE OF SUMMER EXCURSIONS.

The summer is ended, and with it summer excursions will soon be brought to a close. Probably no season has witnessed so many. The seaside and country resorts within a radius of thirty miles have been diligently patronized by crowds of persons compelled to make the city their summer home. Especial efforts have been made to provide the young, the poor, and the sick with fresh air.

A great deal has been said about the sanitary value of these excursions. No one can doubt that the hot and dusty atmosphere of a New York City summer is far from being a tonic. But we think it a good time to start the query whether the daily trips made out of it in the name of health and rest have all the sanitary value claimed for them. We are especially inclined to believe that the much-praised Sunday excursions are, from a sanitary point of view, a humbug. Let doubters make some comparative experiments. On a hot Sunday one takes a crowded car, by which he reaches a more crowded steamer, and, after a crowded ride, is landed at a bustling, noisy hotel. Our excursionist tires himself in trying to find a place to rest, and is further wearied by waiting for an overworked waiter to get him a high-priced dinner. He smokes perhaps; he eats and drinks if he can; and finally crowds his tired way home, reaching it, we venture to say, in nine cases out of ten, vastly more exhausted than the ploughboy of elegiac memory.

This is the dark side of the picture. There are robust frames and happy natures to whom all this is freshness and delight. But we are looking at the excursion as a medicine to the wearied and feeble. For these it has elements which are inevitably injurious. "Crowds kill joy" to many; they kill rest to more. Man becomes easily tired when suddenly thrust into new surroundings. The constant excitation of the senses by novel scenes and crowds of faces makes a drain upon the energies which unconsciously but surely enfeebles them. It is this which counteracts the benefits of cool air and fresh breeze, and which explains the tired feeling that surprises the returning excursionist who has consciously made so little physical or mental exertion. On the very young, a change of environment makes less impression. They are not yet habited to any special routine. But one or two days on the river cannot greatly help an infant. And the way to make a city healthful to this class in the summer is not by floating them once a month down the harbor, nor even by taking them for a few days to the country. This is all very well; but if sanitarians would strike at the root of the matter, they must make the homes and tenements of New York clean and airy and healthful.

THE TOY DESTROYER.

Of the various forces of nature fire seems to have the greatest attraction for boys, and explosive noises seem to be its most fascinating accompaniment. Hence the popularity of the toy pistol. It satisfies the boy's most urgent instincts, and appeases also the lurid fancies excited in him by the penny literature of the streets. With a toy pistol and a five cent novel the boy can easily pose himself as the embryo hero of most thrilling tales.

The peculiar pleasures of this toy, however, are dearly purchased. We recall the injuries and

deaths resulting from its use in London, Baltimore, and this city in particular during the past two or three years. The pistols are cheaply constructed and the explosives are very liable to injure the person firing. Furthermore, the injuries have a marked tendency to induce lockjaw or even a complete tetanus. The records of what toy pistols did in this city on the last Fourth of July were given in THE RECORD (August 26th). There were few public hospitals which did not at that time have some youthful victim of an indiscreet fondness for explosives.

It is quite time that the toy pistol be abolished by law.

Here is an opportunity for the State to protect life with but little trouble. It is its plain duty to suppress what has become a danger as well as a nuisance.

The dangers in its use are being recognized by the public press. A series of cartoons in *Puck* most dramatically illustrates the murderous tendencies of what is sold for a cheap and harmless plaything. Some poetic verses are appended, of which the concluding stanza is most to the point:

"See the little pistol
In the little shop;
See the urchin buy one
With a joyous hop.
See him gaily load it
With a deal of care;
Then see his little head
Flying through the air."

THE EGYPTIAN WAR.

THE preparations for the care of the sick and wounded in the Egyptian war have been very carefully made. The equipments for numerous field hospitals have been furnished and put into use. An Army Hospital Corps of over nine hundred men is already in Egypt and distributed at various posts. A large steamship, the Carthage, has been fitted out as a hospital ship, and accommodations for two hundred and fifty men have been prepared upon her. Surgeon H. Fergusson is in charge with a staff of assistants and four nurses. Her purpose is to transport the wounded to a general hospital at Cyprus or Gozo. Some of the invalids are carried still farther west and left at Malta. A second hospital ship is being fitted out at date of writing.

The medical officers have all been supplied with a pamphlet giving directions as to the special sanitary precautions needed to preserve the health of the troops.

So far, fortune has ordained that most of the sick and wounded should be among the Egyptians, who have no such elaborate arrangements for the care of their unfortunates. The English troops have suffered comparatively little, considering the circumstances about them, either from injury or disease, for a campaign dignified by the name of war. About four per cent. are reported sick.

One of the great dangers to which the soldiers have been exposed has been the endemic hæmaturia of that country. This disease, which frequently afflicts the fellaheen, is produced by drinking the unfiltered water of the Nile. Such water contains an organism *Bilharzia hæmatobia* which is the direct cause of the disease. The English troops, as yet, have escaped any trouble from this source.

A remarkably effective piece of sanitary work deserves mention in connection with the present campaign in Egypt. After the bombardment and capture of Alexandria, and the horrible massacre of its inhabitants, the city was left in a most frightful condition. The dead were unburied, many persons were wounded and sick, and there was a general appearance of ruin and desolation. Numerous dying and dead animals lay about the streets. In addition to it all, the water supply was short. With the hot sun pouring down, there were all the elements present for the generation of a virulent epidemic. Fortunately there were those who understood the danger. A sanitary commission consisting of four local medical men was organized and given authority to act. They at once had the dead buried, large trenches outside the city being used for the purpose. The streets were cleansed, and as the weather was favorable and the water supply increased, no serious amount of sickness took place. We doubt if the value of the work thus done in saving lives has been justly appreciated.

THE YELLOW FEVER EPIDEMIC.

THE fight against yellow fever is being actively waged, and so far has been very like a drawn contest. There has been no great extension of the disease at any single point, while at Pensacola and Matamoras there is a temporary check at least. It has, however, held its own in Texas, and has been thrusting its ugly presence into several new places. At Brownsville the fever has, so far, been kept confined within the cordon. Its activity, however, is not abated at date of writing. The number of cases during the week ending September 4th was 544, with 24 deaths. The total number of cases at this town since the epidemic began is 1,261, with 76 deaths. Thus nearly one-fourth of the whole population has suffered from the disease. The mortality-rate, however, has been surprisingly low. This rate, which in some epidemics reaches 75 per cent., and which rarely falls below 10 per cent., has been at Brownsville only about 6 per cent. As over one-half of the period during which yellow fever epidemics usually last has now expired with no serious extension and no increase in malignancy, we may continue to expect that the country will receive no serious injury from the disease.

Since our last editorial note the fever has appeared in Pensacola, Florida, much to the conster-

nation of that thriving place. The disease is believed to have been imported from Matanzas by the bark Saleto, which arrived July 2d, was quarantined twenty days, then came up to the railroad wharf, and unloaded. On August 10th, the captain and two seamen were sick with the fever. On August 25th, another case was found on board an Italian bark, which had been sixty days in port. A third and fourth case were discovered on another vessel in the harbor. On August 28th, a case was found in the Marine Hospital. It was that of a seaman from a New Orleans vessel, which had arrived two weeks before. Meanwhile eight cases, with one death, had been reported in the city by private physicians. Up to September 2d there were one or two cases reported daily, but the disease seems now to be kept well in hand. There have been in all up to the 4th instant twenty cases, with six deaths—a larger mortality-rate than exists in Texas.

Ten or twelve deaths from yellow fever per week are reported at Havana. Infected vessels have been discovered and quarantined at Boston and Philadelphia. An alleged case of yellow fever was reported as occurring at Lynn, Mass., on the 31st ult., but there was most probably a mistake in diagnosis. The fever is abating at Matamoras.

Reports of Societies.

BRITISH MEDICAL ASSOCIATION.

Fiftieth Annual Meeting, held in Worcester, England, August 8, 9, 10, 11, *and* 12, 1882.

(Special Report for THE MEDICAL RECORD.)

GENERAL SESSION—FOURTH DAY, FRIDAY, AUGUST 11TH.

THE session opened with a discussion upon the

NOTIFICATION OF INFECTIOUS DISEASES.

The point at issue was whether the doctor or the householder should be compelled to notify the authorities upon the occurrence of an infectious disease. The following resolution was at last adopted after much discussion:

"That, in view of the unanimous opinion of all competent sanitary authorities that notification is the indispensable basis of action for arresting the spread of infectious diseases, and of the general testimony as to the satisfactory operation of the Acts which have already been passed by the legislature to make such notification compulsory, this meeting declines to withdraw the approval which the Association has repeatedly expressed in favor of urging Parliament to make the notification of infectious disease generally compulsory, under such conditions as may appear to be, after due inquiry, best calculated to protect the public health."

An amendment was added to this as follows:

"That this meeting earnestly desires compulsory notification of infectious disease, but it wishes to express its opinion that the compulsion to notify should be placed upon the householder as his duty as a citizen, and not upon the doctor."

THE MIDDLEMORE PRIZE

of sixty guineas was then presented by the President, on behalf of the Association, to Mr. William Adams Frost, of London, for his essay upon the "Scientific and Practical Value of Implements in Ophthalmic Medicine and Surgery" made or published within the past three years.

DR. HUMPHREY, of Cambridge, on behalf of the Collective Investigation Committee, reported organization and progress.

DR. WADE, of Birmingham, brought up the report of the

SCIENTIFIC GRANTS COMMITTEE.

During the year the sum of £225 had been expended in helping on scientific researches. The money had been distributed among twelve persons, in sums of from £10 to £25.

Among the reports already made or preparing are the following:

Dr. Thin has been engaged in "Investigations on Methods for Showing the Presence of Bacteria in Epidermic Structures." He has found confirmatory evidence of the existence of a bacterial organism in the hairs in alopecia areata. In his further series of experiments, he still finds that *trichophyton tonsurans*, while it grows freely on the surface of vitreous humor in an incubator, does not germinate when completely immersed in the fluid. He has presented a report on *microsporon furfur*, showing that it remains sterile when cultivations are tried in a variety of suitable media, in which common fungi grow freely. The parasite is therefore not one of the common fungi, but a special fungus, whose only soil yet known is the human skin. He is still investigating Chinese leprosy. He has found, in the skin of Chinese lepers, a bacillus of the same size and form, and with the same staining qualities, as the bacillus lepræ described by Hausen, Neisser, Cornil, and Suchard, and others, on the Continent. Further reports will be published in the *Journal*.

Dr. Chapman's paper on the

VARIATIONS AND DURATION OF THE CARDIAC VENTRICULAR SYSTOLE IN MAN UNDER DIFFERENT CONDITIONS OF PULSE RAPIDITY, TEMPERATURE, ETC.,

was presented at the annual meeting.

His investigations showed that in increased pulse-rate from severe exertion the systole is shortened, and in some cases the shortening was more, proportionately, than the diastole. Thus the pulse-rate in one case, when the experimenter was at rest, was 63 per minute, systole 3.30, diastole 3.90; after severe exertion, the pulse-rate being 115, the systole was 2.20, diastole 3.00.

In another case before bath the pulse-rate was 57.7; systole, 3.50; diastole, 6.90. After a short immersion in a hot chamber, temperature 140° F., the pulse-rate was 62; later, the bodily temperature being 100.7° F., pulse-rate was 80; systole, 2.60; diastole, 5.00.

Dr. G. F. Dowdeswell will soon report his investigations of the "Intimate Nature of the Contagious and Acute Infective Diseases" made during the past year. It has been found among other things that both in the case of the so-termed Pasteur's septicæmia in the guinea-pig and of Davaine's septicæmia in the rabbit, when the exudation fluid and the blood respectively are effectually sterilized by heat, they are no longer toxical nor in any way infective, nor are the characteristic micro-parasitical organisms in either case reproduced.

Mr. North is engaged in experiments upon the

ELIMINATION OF NITROGEN,

As the result of some observations on the elimination of nitrogen during inanition (*Journal of Physiology*, vol. i.), he came to the conclusion that a certain amount of nitrogen can, as it were, be stored in the body, and that, under certain circumstances, this reserve fund can be drawn upon to supply its needs. He has endeavored to discover to what extent this storage of nitrogenous material is possible, and the effect of severe bodily labor on its elimination from the body. The chief points of difference between Mr. North's observations and those of other observers are, the duration of each experiment, the diet, and the amount of exercise taken. The experiments are all made upon himself. Mr. North has been particularly careful in the diet adopted during his experiments.

Mr. A. De Watteville and Dr. Waller have been making some important researches into the

ELECTRO-PHYSIOLOGY OF THE HUMAN NERVES,

with the object of determining whether the same alterations of excitability during and after the passage of a galvanic current which physiologists demonstrate in the exsected frog's nerve, also occur in the living human nerve. For this purpose they chose nerves which are placed superficially, such as the mitral, perineal, etc., and estimated their excitability under various conditions of polar influence, by comparing the amplitude of the muscular contractions registered on the myographion. They showed that the effects produced were not due to any physical causes, such as alterations of current strength, mutual interference of polarizing, and testing currents, and the like, and found that these effects interpreted in the light of Helmholtz's proposition—"that owing to rapid current diffusion in the embedded nerve, a pole of the opposite name to that applied to the surface exists in its immediate neighborhood"—that these effects coincided in the main with those observed on the frog's nerve. Their conclusions are these. 1. There is increased excitability in the portion of the nerve submitted to cathodic influence, diminished excitability in that submitted to anodic influence. 2. With sufficient strength of polarizing current, the catelectrotonic region appears to invade the anelectrotonic region. 3. On opening the polarizing current the diminished excitability of the anodic region passes at once into a state of augmented excitability. The augmented excitability in the cathodic region makes way to a well-marked diminution, gradually followed by a protracted increase of excitability.

At the conclusion of the report it was voted that it be accepted and that a grant of £300 be made for the coming year.

After some miscellaneous business and votes of thanks, the General Meeting was adjourned.

SECTION OF MEDICINE.

Dr. A. S. Myrtle, of Harrogate, read a paper upon

A CASE OF ACUTE ASCENDING PARALYSIS—CHRONIC ALCOHOLISM.

The case was reported not only on account of its rarity, but because it afforded a unique illustration of metastasis of disease. For years the organs which exhibited the poisonous action of alcohol were the liver, stomach, and uterus; all were kept in a state of irritability and hyperæmia; and both liver and uterus were materially enlarged, the latter failing in the performance of its functions, with sterility as the natural result. As soon as the first symptom of spinal mischief made its appearance, the organs previously affected began to show an amount of healthy activity which were very puzzling: the usual sickness and vomiting ceased, the appetite for wholesome food and capacity for digesting the same returned, the tenderness and fulness over the liver gave way, the bowels acted regularly, the urine became healthy, and the function of menstruation natural. The detailed history of the case was then given, which was that of a young married woman aged twenty-two.

Commenting upon the fact that no cerebral symptoms were present, the author quoted a remark of Dr. Allbutt: "I have often seen women given to the abuse of stimulants suffer from severe shooting pains in the legs, and these were always accompanied by great muscular weakness. The spine of women seems to be more affected in alcoholic poisoning than that of men, whose brains become affected instead; so we have spinal paralysis in the one, delirium in the other. Of this I am certain, that delirium tremens seldom appears among women. In my long experience, I cannot recall a single case, and among men I have met with hundreds."

In the discussion which followed,

Dr. Broadbent said that he had seen the case, and did not consider it one of acute ascending paralysis. He considered the case to belong to a group of which he had seen four or five examples besides that of Dr. Myrtle's patient. The disease was a peculiar form of paralysis which he had only met with in women, and as a result of alcoholic excess. The loss of power did not affect the lower extremities first and completely, gradually ascending to the chest and arms, but was more or less present in all the limbs; in the upper extremities the extensors of the wrist were often predominantly affected at first, but later the flexors suffered, and then the hand dropped according as the forearm was pronated or supinated; there was a peculiar softness and flabbiness of the muscles when they were handled, and the very remarkable congestion and swelling of the feet and hands mentioned by Dr. Myrtle when they were allowed to hang down, even for a few minutes, was present. This was, of course, due to vaso-motor paralysis, and probably had much to do with the peculiarities of the affection. All the cases he had seen proved fatal except one.

Others who spoke seemed to agree that it was not a case of acute ascending paralysis.

Dr. Francis Warner, of London, read a paper on

THE STUDY OF THE FACE AS AN INDEX OF THE BRAIN.

In almost all cases, the speaker said, the best indications of the conditions of the central nerve mechanism are its effects as seen in the spontaneous action of the muscles; and it is by the result that that we usually judge of the central condition. Such effects are conveniently spoken of as nerve-muscular signs. Nerve-muscular signs are the best indices of the brain. The change in the brain affects the muscles; these control the position of the visible parts; and, from the facial changes resulting, we gather our information.

We are here, he said, studying the results of cerebral action upon muscles, according to well-understood principles of physiology; while physiognomy

deals mainly with the shape of the brain-case and the passive condition of the face.

The principal movements of the facial muscles are these:

First.—Dilatation and contraction of the facial foramina; probably this corresponds in significance to flexion and extension.

Second.—Elevation and depression of parts. Such conditions are well seen by comparing the two sides of the face in a case of Bell's paralysis.

Third.—Retraction and drawing forward of parts, as in grinning and screwing up the mouth.

Symmetry is a point of especial importance to study. Lack of symmetry in the different zones is very common in nervous people. In the upper zone of the face the occipito-frontales are often seen over-acting in imbeciles and in cases of chorea; sometimes, also, they overact as a mere "chronic nervous habit." Symmetry in this zone is, however, usually maintained. In the middle zone symmetry is less uncommon. It is seen in winking and in ptosis. The important muscles here are the orbiculares oculorum. With megrim, and in conditions of depression, a marked change is often seen in the midfacial zone, due to a fulness about the eyes, especially about the under eyelids; the orbiculares have lost their tone, the skin hangs too loosely, the skin of the lower eyelid, instead of forming a convex surface, passes as a plane from the ciliary margin to the lower margin of the orbit.

In the lower zone, we see the most marked effects of facial spasm or palsy from brain-disease—*e.g.*, in hemiplegia and lesion of the crus cerebri. The muscles of this region are those most commonly seen in spontaneous action in imbeciles.

Dr. Agmondisham Vesey, of Magherafelt, read a paper upon

A CASE OF SPINAL HEMIPLEGIA FOLLOWING GANGRENE OF THE RIGHT GREAT TOE.

A gentleman, aged seventy, previously healthy and temperate, had been suffering for three months from pains in the calves and burning sensation in the feet. In about two weeks after he was first seen the right toe became gangrenous. The superficial veins in the right forearm were hard and filled with clots. Elsewhere the veins were normal. Two weeks later the left arm was completely paralyzed; next day the left leg became involved. The head was in no way affected. A cardiac murmur was present. The right side of the body was anæsthetic, while the left side was slightly hyperæsthetic. The patient died comatose next day. No post-mortem.

The points of interest in the case were these: 1, the tendency to formation of blood-clots; 2, the development of a cardiac murmur (thrombosis); 3, the paralysis of the left arm alone first; 4, the sequence of complete spinal hemiplegia on the next day; 5, the absence of any form of cerebral paralysis; 6, the general anæsthesia of the right side; 7, the limited hyperæsthesia of the left side; 8, the rapid ending of the case within thirty-six hours of the completed paralysis of the left half of the body.

SECTION IN SURGERY.

At the Second Session Mr. Bryant related a case of

DOUBLE POPLITEAL ANEURISM,

of which one was cured by pressure, and the other by Speir's artery constrictor with antiseptic (not aseptic) precautions.

Mr. Thompson related the history of his case of

LIGATURE OF THE INNOMINATE ARTERY

for subclavian aneurism, and showed the specimen. Subsequent speakers were quite agreed that the fatal result was not dependent upon the ligature of the artery, but was due to ulceration of the drainage-tube sinus, probably opening up the vertebral artery; the ligature (ox aorta) had acted perfectly.

Mr. A. H. Dolman reported a

CASE OF TRAUMATIC AXILLARY ANEURISM

successfully treated by ligature of the subclavian artery. So much difficulty was met with in getting the thread around the artery (the left), that the clavicle was divided to expose the vessel.

Mr. Barwell showed the aneurism needle he had had made for cases of this kind, and expressed his belief that had it been employed division of the bone would have been unnecessary.

Mr. Bartleet read a paper on five cases of

LIGATURE OF LARGE ARTERIES.

One was a case of femoral aneurism, for which he tied the common femoral trunk with chromic catgut; the wound did not remain aseptic, and secondary hemorrhage came on. The wound was then opened up, when it was found that the artery had separated one-tenth of an inch above the ligature. The two ends of the vessel were then tied with a hempen thread. Again there was repeated secondary hemorrhage, for which the external iliac artery was ligatured with whipcord, with a final successful result.

Mr. Bennett May related a case of

LIGATURE OF THE EXTERNAL ILIAC ARTERY

and discussed the best material for ligatures, and stated that there was more difficulty in getting primary union of a wound when chromic catgut was used than when carbolic gut was employed, and he expressed his preference for common catgut soaked for a long while in carbolic oil.

Mr. Robson showed an apparatus for obtaining an

ANTISEPTIC ATMOSPHERE

to replace the carbolic acid spray in surgical operations, asserting that while the carbolic acid spray was aseptic, it was not antiseptic, and was also harmful. Mr. Robson advocated the value of an antiseptic, dry, non-poisonous atmosphere. This he obtains by pumping air through cotton-wool to purify it from all suspended impurities, and then through eucalyptus oil. To show the antiseptic value of an atmosphere of this kind, he had taken several large, wide-mouthed glass jars and poured a little of one of these oils into each, and had then suspended jars of sterilized hay infusion in them, and had removed their cotton caps for various periods; in every instance except one bacteria had not subsequently developed in the infusion. He had also used it for surgical purposes, and Mr. Spencer Wells had employed it during the excision of a mamma, and had expressed himself pleased with it.

Mr. R. H. B. Nicholson recorded a successful case of gastrostomy.

Mr. George Elder related a successful case of nephrotomy and nephrectomy for scrofulous pyelitis.

Mr. Lawson Tait showed a girl from whom he had excised a kidney through the linea alba; he also showed the kidney, which was sacculated, and contained a large calculus.

Dr. Cullingworth related a case of

NEPHRECTOMY

by abdominal section for hydronephrosis, in which the patient died from shock twelve hours after the operation; and in reference to this case Mr. Tait remarked that he should never attempt nephrectomy for renal cysts, as the operation of incising and draining these cysts proved so successful in his hands.

MR. LAWSON TAIT recorded a third successful case of

CHOLECYSTOTOMY,

and showed a large number of gall-stones he had removed from the gall-bladder. The gall-bladder formed a prominent abdominal tumor, and it was an interesting feature of the case that although the cystic duct was completely obstructed, there had not at any time been jaundice. He opened the gall-bladder, and stitched the edges of the wound in it to the abdominal incision, and extracted a large number of stones. The discharge had continued mucous until that week, when bile had made its appearance, showing that the duct had become patent again. Mr. Tait therefore intended to freshen the wound and close the sinus.

Mr. Lawson Tait then read a paper on

ONE HUNDRED CONSECUTIVE CASES OF OVARIOTOMY

performed during the last thirteen or fourteen months, and in which he had not used any kind of antiseptic measure. Of these, three patients died, one from choking during vomiting, and two from venous thrombosis, starting at the pedicle and spreading quite up to the heart. Six of the patients were pregnant at the time of operation, one in addition had acute peritonitis—all got well; one of them miscarried, and five were delivered of living children at term. Four patients had acute peritonitis at the time of operation, and all recovered. In two the tumor was solid fibroma of the left ovary; in ninety-eight it was cystoma. Of the latter eleven were parovarian cysts, sixty were cysts of one ovary only, and among these were the three deaths, and twenty-seven were cysts of both ovaries. In fifty-three cases there were serious adhesions, but he had not found that this fact in any way added to the mortality. Of the three fatal cases there were no adhesions in two, and slight parietal adhesions in the third. In seventeen cases the tumor was sessile. All these cases were dressed with dry absorbent cotton-wool; in about one-twentieth of the cases a part of the wound opened, and then it was dressed with zinc ointment or red lotion. Mr. Tait attributed his improved mortality: (1) To the total abandonment of Mr. Spencer Wells' clamp; (2) to the thorough cleansing of the peritoneum, as recommended by Keith; (3) to the draining of the peritoneum, as recommended by Keith; (4) to increased personal experience; (5) to the diminished number of cases which had been previously tapped; the two of his patients who had died from thrombosis had been tapped, one sixteen and the other thirty times; he believed that if tapping was never adopted there would be no mortality after ovariotomy, except from tetanus and similar outstanding risks; (6) the complete abandonment of antiseptic treatment; (7) the establishment of hospital discipline and hygiene. This he deemed of so much importance that in only exceptional circumstances would he consent to operate in private houses.

The discussion which followed was quite an active one, and turned upon the subject of antiseptics.

MR. COATES said that it was very difficult to harmonize Mr. Tait's statements with those of Dr. Stokes earlier in the day in reference to antiseptics. But his experience in general surgery was that while before his adoption of the Listerian treatment he did not obtain primary union of wounds in one per cent. of his cases, since that adoption he obtained it in every case.

MR. M. THOMSON referred to the great diminution in the mortality of his cases that Mr. Tait observed when he first adopted the antiseptic treatment, and maintained that the results of general surgery abundantly proved the value of this treatment.

DR. BANTOCK, in opposition to Mr. Tait, maintained that adhesions of ovarian tumors to intestine and pelvic organs are serious complications of ovariotomy. He had given up antiseptics, and he had not had more septicæmia than other operators who had used it, and he asserted that Listerism had not freed us from septicæmia.

DR. SUTTON had spent a considerable period in studying European surgery, and he stated that in Berlin, Vienna, Halle, Kiel, and Leipsig, he found antiseptics everywhere, and such results obtained that on coming to England he dared not have opened the abdomen without employing them. He then went to see Keith's practice, and his views were changed; for Dr. Keith and his son (who has done five cases) had had a run of fifty-five cases of ovariotomy with only one death; alluding to Dr. Keith's abandonment of Listerism, he said that he had Dr. Keith's authority for stating that he had never used the carbolic spray stronger than was recommended by Prof. Lister. He had also seen Mr. Tait's practice for three or four weeks, and he had been very careful to watch his practice closely; but he had only seen one of his wounds in which there was a drop of pus—one already mentioned by Mr. Tait.

DR. ED. TAYLOR, who was for some years Mr. Spence's assistant, said that antiseptic surgery was often an excuse for careless surgery.

MR. TAIT in conclusion criticised the frequent changes in the methods adopted by those who employed Listerism.

SECTION IN PATHOLOGY.

The Section was opened with a debate on "The Pathology of Diabetes." The debate was somewhat unsatisfactory, owing to the absence of Prof. Hamilton, who had been expected to open it.

DR. STEPHEN MACKENZIE spoke of diabetic coma and thought that it was due to a complex of causes, but in most cases that acetonæmia was the leading factor, while only a small proportion were due to fat embolism.

DR. SAUNBY said that he had rarely been able to demonstrate fat embolism in diabetic coma.

DR. SHINGLETON SMITH contended for the nervous origin of diabetes, and related a case in point.

Papers were read by DR. SAUNBY on "Changes in the Sympathetic in Bright's Disease," and by DR. GOWERS on "Certain Pathological Changes in the Spinal Cord."

At the second meeting MR. JONATHAN HUTCHINSON opened a debate on the

ETIOLOGY OF TUMORS,

and contended for their local origin. He was followed by SIR JAMES PAGET, who stated his well-

known views on this subject; and by MR. BUTLER, DR. THIN, and others, who showed microscopical preparations.

MR. R. WILLIAMS read a paper on "Sarcoma of the Bladder."

At the closing meeting, DR. SANGSTER read an exhaustive paper on

RODENT ULCER,

in which he tried to establish the fact that the disease is not primarily connected with the sweat-glands, but that the morbid change starts from the Malpighian layer and outer sheath of the hair-follicles.

DR. THIN disputed this view.

The rest of the morning was occupied with a demonstration of various forms of bacilli, which excited a good deal of interest, and was one of the most successful events of the meeting.

DR. HERON showed Ehrlich's process of preparing tubercle bacillus, and he was followed by DR. GIBBES, who demonstrated his process of preparing the same bacilli, which was described in *The Lancet* of August 5th. It was very evident that this process, while decidedly simpler than Ehrlich's, was also more effective, and is, therefore, more useful.

DR. S. MACKENZIE also showed a specimen of tubercle bacillus prepared by Goltdammer's method.

DR. SHINGLETON SMITH showed bacillus anthracis, and DR. THIN the bacillus of leprosy.

SECTION IN OBSTETRICS.

DR. BANTOCK read a paper on "Hysterectomy," and related a number of cases operated upon by himself. In the debate Drs. G. Williams and Wallace strongly opposed the operation.

DR. EDIS read a paper on "Menorrhagia." He was followed by DR. C. H. ROUTH with a paper on "Dysmenorrhœa Associated with Gonorrhœa."

SECTION IN OPHTHALMOLOGY.

DR. EDWIN ANDREW opened the discussions with a paper on the

EXTRACTION OF CATARACT IN THE LENS CAPSULE.

He described new instruments for separating the lens from its capsule by tearing the suspensory ligament. To obviate pressure, he had abandoned the speculum and kept the lids apart by passing a thread of catgut through one or both lids.

Dr. Andrew advocated a more frequent use of his method.

In the discussion, the opinion was developed that this method was especially applicable in over-ripe cataracts and in aged persons, in whom the suspensory ligament has a less resistance.

MR. ANDERSON CHRITCHETT read a paper on the

TREATMENT OF LAMELLAR CATARACT.

He advocated the formation of an artificial pupil, by Tyrell's hook, in preference to removal of the lens.

DR. ARTHUR BENSON read a paper on

PARTIAL TRICHIASIS,

in which he recommended the removal of the offending hairs, with needles, by electrolysis.

MR. NETTLESHIP and MR. PRIESTLEY SMITH reported three cases of

NEURITIC ATROPHY OF THE OPTIC NERVE,

followed by continuous dropping of a watery fluid from the nose. The fluid possessed negative characters and was not cerebro-spinal. In one case there was probably a growth in the nose; in another a mucous thickening. In one case there were curious nervous symptoms, *e.g.*, drowsiness and stupor. The flow then ceased. During one of these attacks the patient died.

MR. NETTLESHIP opened a discussion on "The Value of Eye Symptoms in the Localization of Brain Disease." The speaker thought that in most cases of hemianopia the lesion, as in hemiachromatopsia, is higher up than the optic tracts.

SECTION IN PUBLIC MEDICINE.

DR. NORMAN KERR read an important paper upon the

PUBLIC MEDICINE ASPECTS OF THE ALCOHOL QUESTION.

His object was to show the amount of sickness and death caused by alcohol. Some diseases, he said, were caused by alcohol alone, as delirium tremens, dipsomania, and alcohol poisoning, acute and chronic. Some, which arose from other causes, sometimes were caused by alcohol directly, as alcoholic phthisis, gout, and paraplegia. Alcohol might also be a main contributory factor, as in fatal frost-bite and sunstroke after drinking. The proportion of sickness and death from alcohol had been shown in the Government returns of the Indian Army for 1849. The mortality of the temperate was double and that of the intemperate quadruple that of the total abstainers. The abstaining deaths were 11.1 per 1,000; the temperate 23.1; and the intemperate 44.5. The admissions of the abstainers were only 10.7 per 1,000 less than those of the temperate, showing that the diseases of the former took a milder form. Insurance companies were so satisfied of the superior healthfulness of the abstinent, that one had paid the abstainers insured 23 per cent. additional bonus, and another offered an extra bonus of 20 per cent. The influence of alcohol on the death-rate was well illustrated in the Registrar-General's report for 1880.

From this report it could be seen that in every class except one the mortality had steadily diminished; but in Class III. the mortality had as steadily increased. In this class the principal increase had been in deaths from diseases of the brain and nervous system, of the organs of circulation, of the respiratory organs, of the liver, and of the kidneys. These were precisely the organs most apt to be seriously affected by indulgence in alcohol. Dr. Kerr had estimated the annual deaths from personal intemperance in the United Kingdom at 40,500. Others made it larger. The indirect fatality by violence, disease, poverty, etc., arising from the intemperance of others, would probably raise the number to 120,000 or 200,000. For the cure of dipsomania, total abstinence was indispensable. Heredity was the chief predisposing cause. The marked increase in the variety and consumption of unintoxicating beverages was an aspect of the question which called for the consideration of students of public health, as an increased use of non-intoxicants was a favorable omen of the future improved sobriety and consequent health of the community.

The second meeting was devoted to a discussion on the "Compulsory Notification of Infectious Diseases."

Correspondence.

ANOTHER REMARKABLE CASE OF TRANCE LETHARGY.

To the Editor of The Medical Record.

Sir: I have lately had opportunity to see the extraordinary case of *natural* trance now exciting so much attention in the Beaujon Hospital, Paris.

It resembles in its history and in many of its phenomena the case of trance lethargy in Pennsylvania that aroused so much interest in our country, and which is described by me in The Medical Record, page 513, 1881, and also in my brochure on "Trance and Muscle Reading," page 10.

On account of the resemblance in the two cases, I write this preliminary note.

I presume the details of the Paris case will be published in the medical journals.

The patient, a comparatively young woman, was picked up in one of the streets of Paris in a condition of supposed intoxication. She remarked that she had been drinking too much beer. Since that time (eighty days) she has not spoken a word, but has lain unconscious, or apparently unconscious. *Fifty-seven days after admission she was delivered of a five months' child, and apparently was unconscious of the act of parturition.* This is the one unprecedented fact of the case.

A few days before I saw her, douches had been applied by the suggestion of Dr. Charcot. The second douche had the effect to partially bring her out of her condition. Her pulse, before normal, was 100 at the time I saw her. Before, she was fed like a baby, like the case described by me. She now takes food with her hand, and she hears and responds automatically to commands. It is said she cannot stand or walk; but I do not know whether thorough experiments have been tried in that direction.

The nutrition of the body is well preserved, just as in the case of the Pennsylvanian, who was in this condition one hundred and sixty-nine days, or more than twice as long as this Paris case.

The last I heard of the Pennsylvanian case was that he had recovered, but was either insane or a border-liner. He was, however, able to work and mingle with the world. It is probable that such will be the issue of the present case, provided she has sufficient physical strength to endure and keep from dying.

As I have elsewhere stated ("Trance States following Inebriety," by Dr. Crothers—Introduction), these cases are not unconscious in the true sense of the term, but they lack *rememberable consciousness;* they know, in a dim way, *at the time*, what they are doing, but are unable to recall what they have done.

If this woman should recover, she would not remember anything about her parturition.

Her condition is mental, the physical phenomena being merely incidental, and if the brain could be examined we should obtain no more information than from the brain of Guiteau.

The Germans apply the term katatonia to these and similar cases. The term is unfortunate and misleading, like scores and scores of other terms that have been applied to these trance states. No term is needed beyond the oldest and simplest word trance, which always has been, and always will be used.

As is now well known to American physicians, trance lethargy can be produced *artificially.*

In Paris, Charcot has made many experiments in that direction during the past few years.

George M. Beard, M.D.

Note.—I wrote a few lines the other day from Paris in reference to the case of trance lethargy. I have since learned that the patient recovered her speech a few hours after I saw her, and on the evening of the same day, the eighty-second day of her trance.

She says that her name is Marcelline Bertrand, and that she is thirty years of age. Her temperament is mystic, and she had at one time been in a convent. After leaving the convent she served as a domestic, and was seduced. Her mistress, then living in Tréport, perceiving that she was *enceinte*, turned her away.

She professes no recollection of coming to Paris from Tréport, up to the time that she was found in the street; but has been conscious of what has been taking place since that time, including her accouchement, although unable to speak or move.

G. M. B.

Geneva, August 6, 1882.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 27, 1882, to September 2, 1882.

Alven, Chas. H., Major and Surgeon. Granted leave of absence for three months. S. O. 196, C. S., A. G. O.

Barrows, Chas. C., Assistant-Surgeon. Assigned to duty at Fort Grant, A. T. S. O. 130, Dept. of Arizona, August 21, 1882.

Bill, J. H., Major and Surgeon. Granted leave of absence to December 1, 1882. S. O. 196, A. G. O., August 24, 1882.

Brown, J. B., Lieutenant-Colonel and Surgeon. Granted leave of absence for six months on surgeon's certificate of disability. S. O. 200, A. G. O, August 29, 1882.

Egan, P. R., Assistant-Surgeon. Assigned to duty at Fort Bowie, A. T. S. O. 134, Dept. of Arizona, August 25, 1882.

Hubbard, V. B., Major and Surgeon. Assigned to duty at Fort Wingate, N. M. S. O. 172, Dept. of the Missouri, August 28, 1882.

Macauley, C. N. B., First Lieutenant and Assistant-Surgeon. Assigned to temporary duty at Fort Columbus, N. Y. S. O. 147, Dept. of the East, August 25, 1882.

Munn, C. E., Captain and Assistant-Surgeon. The leave of absence granted him in S. O. 117, July 28, 1882, Dept. of the Missouri, is extended two months. S. O. 196, C. S., A. G. O.

Owen, Jr., Wm. O, First Lieutenant and Assistant-Surgeon. Assigned to temporary duty at Vancouver Barracks, W. T. S. O. 114, Dept. of the Columbia, August 11, 1882.

Skinner, J. O., Captain and Assistant-Surgeon. To take charge of Medical Director's office, Dept. of Arizona. S. O. 131, Dept. of Arizona, August 22, 1882.

Smith A. K., Major and Surgeon. Granted leave of absence for one month on surgeon's certificate of

disability. S. O. 131, Dept. of Arizona, August 22, 1882.

WAKEMAN, W. J,, First Lieutenant and Assistant-Surgeon, now at Omaha, Neb., to report to the Commanding Officer, Fort D. A. Russell, Wyoming, for duty. S. O. 88, Dept. of the Platte, August 25, 1882.

Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — **Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending** September 2, 1882.

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
August 26, 1882.	1	29	29	5	9	45	0	0
Sept. 2, 1882.	1	32	24	5	9	31	0	0

THE FEVER AT SEABRIGHT, NEW JERSEY.—Further investigation by the State and Local Health Boards of the hotel where typhoid fever appeared makes it possible, though not certain, that the fever was due to bad drainage. The wastes of the hotel were disposed of by two cesspools with overflows into the river close by. The overflow in one case was stopped up, and the house pipe leading to it was not trapped, though the soil pipe was carried above the roof with end open. The soil of the cellar was somewhat polluted, but the drinking water was good and not contaminated so far as is ascertained.

THE VACATION OF A SUCCESSFUL PRACTITIONER.—*Wife* (to doctor just home from a week's hunting).—"Well, James, did you shoot anything?"

Doctor (sadly).—"No. Awfully bad luck; never killed a thing."

Wife (who knows him—sweetly).—"My dear, you'd have done better if you had stayed at home."

HOG CHOLERA, or the infectious pneumo-enteritis of swine, has appeared in the vicinity of Reading, Pa.

THE TEXAS CATTLE FEVER has appeared in Penobscot County, Maine, eight animals having so far died from the disease.

THE SOCIAL SCIENCE ASSOCIATION met during the past week at Saratoga.

HEALTH ALONG THE NEW JERSEY COAST.—The authorities of Monmouth County, N. J., have forbidden any sewerage or refuse to be drained into the Shrewsbury River.

THE PRINCE OF WALES AND MEDICINAL WATERS.—That great and good man, the Prince of Wales has gone to Germany to take the waters. The London *Times* thereupon thus sweetly effervesces: "The Prince of Wales needs a holiday, though he may not be aware that he wants it. That he has submitted to take it at the instance of medical wisdom, which considers mental as well as physical circumstances, is a fresh argument of his royal good sense. If he is directed to temper his vacation with a course of mineral waters, he may be sure his system is condemned to imbibe no more salts and carbonates and alkalies than will constitute the minimum qualification for a moderate respite from the tyranny of social observances."

A HOMŒOPATHIC CRITIC CRITICISED.—Certain of our esteemed contemporaries who have charged Dr. Piffard with being an insidious defender of homœopathy should read his caustic criticism of a Dr. Price in the *New York Medical Times*, the leading journal of liberal homœopathy. Among other things, he says: "Dr. Price says: 'Probably the fact may never have occurred to Dr. Piffard that a doctrine of Hahnemann and a law of nature are not necessarily synonymous.' I do not know what I have written to lead Dr. Price to the above remark. The laws of nature (relating to drug action) are mostly unknown to us, but the doctrines of Hahnemann are in black and white, and their meaning cannot be easily misunderstood. The three most prominent of his doctrines are: 1st, that *all* diseases should be treated according to the principles of *similia;* 2d, that the thirtieth dilution is the *best* dose; 3d, that chronic diseases are the emanations of either syphilis, sycosis, or psora. The man that believes these propositions is a Hahnemannian, and may, if he chooses, call himself a homœopathist. The man that doesn't believe them is not the former, and should not *call himself* the latter. Nine-tenths of those who are known as homœopaths do not believe the doctrines above noted, or at least do not appear to act on them, and their proper course as physicians, at the present medico-political juncture, ought to be clear to them."

THE UNIVERSITY OF WÜRZBURG celebrated its three hundredth anniversary this month. In honor of this event, honorary distinctions were conferred—sparingly. Four gentlemen—Prof. Quincke, of Heidelberg, Prof. Clausius, of Bonn, Prof. Charcot, of Paris, and Herr Bdaumüller, the Vienna bookseller—were recipients of honorary M.D. degrees.

THE AMERICAN DERMATOLOGICAL ASSOCIATION, at its annual meeting in Newport, September 1st, elected the following officers: *President*—Dr. R. W. Taylor, of New York; *Vice-Presidents*—Dr. J. E. Atkinson, of Baltimore, and Dr. A. R. Robinson, of New York; *Secretary*—Dr. Arthur Van Harlingen, of Philadelphia; *Treasurer*—Dr. George H. Rohe, of Baltimore. The new members elected were Drs. P. A. Morrow, of New York, and W. H. Stillwagren, of Philadelphia. The next meeting of the Association will be held at Lake George on the first Wednesday in September, 1883.

THE CANADIAN MEDICAL ASSOCIATION met at Toronto this week, September 6th, 7th, and 8th. Dr. Fenwick, of Montreal, President, occupied the chair. There was a very good attendance and about twenty papers were read, some of which were of a high standard. A brilliant reception was given by the profession on Thursday evening. Altogether the meeting was a most successful and satisfactory one.

INOCULATION OF BOVINE TUBERCULOUS MATTER IN MAN.—Two Greek physicians have recently made a direct experiment to see whether bovine tuberculosis could be inoculated in man. The subject of the experiment was a common laborer, who, in consequence of arterial occlusion, was slowly perishing from progressive gangrene of the leg. In other respects the patient was healthy, and a careful examination showed that the lungs were in normal

condition. As he refused to submit to the amputation of the limb, pronounced necessary to save his life, his medical attendants decided to test by direct experiment whether tubercle can be propagated from phthisical cows to man by inoculation. A quantity of tuberculous matter was accordingly injected into the circulation, whether with or without consent is not specified. The man lived about six weeks, then died of the blood-poisoning inseparable from progressive gangrene. The autopsy disclosed the existence of well-defined tuberculous deposits, without abscess or other disease of the pulmonary organs, very small, evidently very recent, and, as the daring experimentalists argued, the direct result of the inoculation.

The Philadelphia Presbyterian Hospital has just received a bequest of $10,000 by the will of the late George W. Musgrave, D.D.

The Sanitary Condition and Endemic Diseases of Egypt.—A correspondent of the *British Medical Journal* writes that up to a recent date the sanitary condition of Alexandria was good. After the bombardment a sanitary commission was appointed, by whose labors the dead were buried and the streets cleaned. The endemic hæmaturia, which is still the scourge of the fellaheen population who drink the unfiltered water from the Nile and canals, is one of the diseases to which our soldiers will be exposed, and against which it will be difficult for them to guard. Nearly three-fourths of the natives in some parts of the Delta suffer from this disease; while Europeans living in the same locality, who use none but well-filtered or well-boiled water, escape it. Any European who has contracted the disease has, in my experience, always confessed to having habitually used the muddy unfiltered water from the canals; and there can be little doubt that the *Bilharzia hæmatobia* finds its way into the system by the water. The disease prevailed among the French troops of the expedition of 1800.

A Therapeutical Failure.—The attempt to secure harmony in C(h)orea.

A Student of Women.—A French physician advocates some novel theories regarding women, and claims to know about them as well as anyone can who has dissected them much and loved them much!

Obligatory Vaccination in Switzerland.—Vaccination has been heretofore obligatory in Switzerland. By a recent vote the law was annulled. The vote was as follows: In favor, 62,522; against, 225,730. There will no doubt be some noisy cackling over this among the anti-vaccinators. The advisability of compulsory vaccination, however, is questioned by many, if not most sanitarians, outside of England.

The French Association for the Advancement of Science met this year at La Rochelle, on August 24th, for its eleventh session. M. Janssen presided.

An Important Literary and Scientific Discovery is announced from Salonica. The works of the celebrated physician, Galen, which were supposed to have been lost, have been discovered by M. Papageorges. They are in manuscript; date from the fifteenth century, and appear to have originally formed 248 sheets; 144 are in good condition, 24 are mutilated or worm-eaten, and 80 are missing.

No Appointment to the Chair of Morphology, left vacant by the death of Professor Balfour, will be made.

Is it Good for Nursing Women to Drink Beer?—At the camp meeting of the Women's National Christian Temperance Union, recently held at Ocean Grove, N. J., the Tabernacle was well filled at each of the four daily sessions, the ladies forming nine-tenths of the audiences. One of the interesting features was a "question box," in which questions were put on the first day to be answered on the second. One of the questions was, "Is it good for nursing women to drink beer?" It was answered by a member of the Union, Yankee fashion, by asking another question, "What is the condition of the milk of cows fed upon the refuse of breweries?" The questioner apparently was fully satisfied.

"St. Jacob's Oil" appears to be a feeble and badly made aconite liniment, and it consists mainly of water, ether, alcohol, turpentines, and a small proportion of aconite with red coloring matter.—Squibb's *Ephemeris*.

Substitution in Prescriptions.—The practice among the Philadelphia druggists of substituting cheaper medicines for the ones called for in prescriptions is said to be very common.

Belladonna Poisoning Treated by Bromide of Potassium.—Dr. Dorr (*Pacific Med. and Surg. Journal*, July, 1882) reports the case of a child, two and one-half years old, who was poisoned by belladonna. Opium alone apparently being without effect, 8 grains of the bromide was given every half hour. After taking 32 grains the child became quiet and went to sleep. In a few days she was entirely well.

How to Use Filix Mas.—The success of certain German "worm doctors" in using extractum filicis led Herr Dietrich to suppose that the best results are obtained when castor oil is administered immediately after the extract, instead of waiting an hour or two, the extract being more likely to reach the worm undecomposed and less likely to irritate the stomach during its rapid passage. Upon experiment this was confirmed (*Pharm. Zeit.*); in fact, the most favorable results were obtained when the extract and oil were administered together. This, according to Herr Dietrich, is most conveniently done in flexible capsules, each containing 1 gramme of extract and 2 grammes of oil. A dose consisting of six such capsules, preceded as usual by a laxative, has been found quite effective.—*Med. Press and Circular*.

The Small-pox Epidemic at Cape Town is reported to be assuming larger proportions.

Novel Method of Suicide.—On May 26th, Sarah Newman, in the Cork Hospital for Women and Children, committed suicide by stuffing her stocking down her throat so firmly that when discovered it was extricated only with great difficulty. It was done so quietly during the night that the occupants of the next beds were totally unaware of anything amiss until the morning.

Iodoform in Diabetes.—Prof. I. Moleschott, of Rome (*Wien. Med. Woch.*), in a lengthy article gives a careful analysis of the treatment of diabetes mellitus with iodoform. He is of opinion that it is of decided advantage, and exerts a greater control over the amount of sugar than the amount of fluid passed. His formula is: iodoform, 1 gr.; ext. lactuc. sat., 1 gr.; cumarin, 0.1 gr.; gummi acac. q. s.; ft. pil. 20. One twice a day, increasing to two four times a day.

Original Communications.

UTERINE AND VAGINAL DISCHARGES.[1]

By JAMES B. HUNTER, M.D.,
SURGEON TO THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK, ETC.

It is not my intention in this paper to treat of the whole subject of uterine and vaginal discharges. I wish only to present a few of its more prominent features, with especial reference to the therapeutic measures I have found most useful in some forms of what is known as "leucorrhœa." Leucorrhœa, so-called, is one of the commonest symptoms for which medical advice is sought, and perhaps for that very reason it is often the subject of a routine treatment that is as likely to do harm as good. I shall have nothing to say of the normal menstrual discharge, and very little of hemorrhagic discharges, or of those due to venereal disease, but shall endeavor to show the importance of discriminating clinically between the different forms of leucorrhœa, varying widely as they do in pathological significance. Unless we carefully consider all the other symptoms in the case of a patient who complains of leucorrhœa, we cannot possibly prescribe intelligently. Much harm may be done by too vigorous treatment of a simple vaginal catarrh; while, on the other hand, regarding only the fact that there is a discharge from the vagina, some serious disease of the uterus may be neglected. Between these two extremes we find a great variety of discharges, very different in their history and character, and requiring different treatment. It will be sufficient for my present purpose to divide leucorrhœa into three varieties:

1. Vaginal.
2. Cervical.
3. Uterine.
